Background. High rates of second-line antiretroviral treatment (ART) failure are reported. The association with resistance and nonadherence on switching to second-line ART requires clarification.

Methods. Using prospectively collected data from patients in South Africa, we constructed a cohort of patients switched to second-line ART (1 January 2003 through 31 December 2008). Genotyping and drug concentrations (lamivudine, nevirapine, and efavirenz) were measured on stored samples preswitch. Their association with viral load (VL) <400 copies/mL by 15 months was assessed using modified Poisson regression.

Results. One hundred twenty-two of 417 patients (49% male; median age, 36 years) had genotyping (n = 115) and/or drug concentrations (n = 80) measured. Median CD4 count and VL at switch were 177 cells/ μ L (interquartile range [IQR], 77–263) and 4.3 log₁₀ copies/mL (IQR, 3.8–4.7), respectively. Fifty-five percent (n = 44/80) had subtherapeutic drug concentrations preswitch. More patients with therapeutic vs subtherapeutic ART had resistance (n = 73): no major mutations (3% vs 51%), nonnucleoside reverse transcriptase inhibitor (94% vs 44%), M184V/I (94% vs 26%), and \geq 1 thymidine analogue mutations (47% vs 18%), all $P = .01$; and nucleoside reverse transcriptase inhibitor (NRTI) cross-resistance mutations (26% vs 13%, $P = .23$). Following switch, 68% (n = 83/122) achieved VL <400 copies/mL. Absence of NRTI mutations and subtherapeutic ART preswitch were associated with failure to achieve VL <400 copies/mL.

Conclusions. Nonadherence, suggested by subtherapeutic ART with/without major resistance mutations, significantly contributed to failure when switching regimen. Unresolved nonadherence, not NRTI resistance, drives early second-line failure.

Keywords. second-line antiretroviral therapy; adherence; resistance; virological failure.

The management of first-line, nonnucleoside reverse transcriptase inhibitor (NNRTI)-based antiretroviral

treatment (ART) failure is challenging in resource-limited settings. In settings with viral load (VL) monitoring but without resistance testing, guidelines recommend excluding drug interactions and toxicity, intensifying adherence support, and switching to second-line, boosted protease inhibitor (PI)-based ART if a second VL remains elevated [1–3]. This strategy aims to optimize outcomes on second-line ART by ensuring that nonadherent patients with or without drug resistance mutations (DRMs) receive adherence support and that patients with resistance switch regimens in a timely manner.

Nevertheless, under programmatic conditions, high rates of second-line virological failure are reported [4–8]. Delayed switching to second-line ART and consequent accumulation of nucleoside reverse transcriptase inhibitor (NRTI) mutations may contribute [9–14]. Studies indicate that only 17%–53% of patients have switched regimen 12 months following virological failure [9, 15]. Although resistance patterns on identification of virological failure are well described, few data exist on resistance patterns on switching regimens [6, 14, 16] and the influence of nonadherence on such patterns [17–19]. Also, few studies have explored the impact of NRTI mutations and the resultant loss of regimen activity on empirically prescribed second-line ART [4, 16].

Nonadherence on second-line ART is increasingly considered the main driver of early second-line failure [4–7]. Although poor tolerability of PIs may contribute to suboptimal adherence, it is also possible that attempts to intensify adherence support during first-line virological failure were unsuccessful, or not sustained. Measuring the success of adherence interventions is problematic. Healthcare workers' (HCW) assessment and patients' self-report overestimate adherence [20–23], and although drug refill is a reasonable marker of cumulative adherence, it does not measure adherence at a set time-point (eg, following adherence interventions). Alternative markers include the absence of DRMs, or subtherapeutic drug concentrations [24, 25]. Sigaloff et al reported no major DRMs in 12% of patients switching regimens [14]; however, no studies have determined drug concentrations at time of switch.

In a South African treatment program, this study describes the contribution that resistance and nonadherence, as determined by subtherapeutic drug concentrations and the absence of major DRMs, make to first-line virological failure on switching regimens, and investigates the impact of NRTI resistance and nonadherence on response to second-line ART.

METHODS

Study Design and Setting

This retrospective cohort analysis used prospectively collected clinic data and stored plasma from patients enrolled in a multi-site workplace and community ART program managed by the Aurum Institute, South Africa [26, 27]. Patients were eligible for ART, free of charge, based on World Health Organization clinical staging and CD4 count criteria. First-line ART comprised efavirenz (EFV) or nevirapine (NVP), lamivudine (3TC), and zidovudine (ZDV) or stavudine (d4T). In 2008, tenofovir (TDF) replaced zidovudine (ZDV) in the workplace program. Guidelines recommended a switch to second-line ART (boosted lopinavir [LPV], didanosine [ddI], and ZDV or abacavir [ABC]), if, following adherence counseling, a second VL measurement remained >1000 copies/mL. CD4 count and VL were monitored at baseline and 6-week and 6-month

intervals after commencing or switching regimen. One of 2 central laboratories routinely stored excess plasma at –80°C.

Study Population

Inclusion criteria were age ≥ 15 years, switched from first- to second-line ART between 1 January 2003 and 31 December 2008, VL >400 copies/mL at switch with available stored plasma (6 months before to 1 week after switch), and potential for at least 15 months of follow-up (data included up to 31 March 2010). Stored samples, from patients with VL >400 copies/mL 12 months (SD, 3 months) following switch, were also analyzed.

Laboratory Methods

Human immunodeficiency virus (HIV) RNA was assayed using polymerase chain reaction (Amplicor HIV-1 Monitor Test, Roche Diagnostics) and genotyping performed on stored plasma using a modified validated in-house assay [28]. Mutations were identified using the Stanford HIVdb genotypic resistance algorithm (<http://hivdb.stanford.edu/>) with mixtures reported as mutant genotypes. HIV type 1 (HIV-1) subtype classifications were performed using Rega version 2.0. Plasma drug concentrations were measured using a protein precipitation procedure to extract the drugs, and analyzed using a validated liquid chromatography–tandem mass spectrometry assay. The accuracy and coefficient of variation statistics for 3TC, EFV, NVP, and LPV during sample analysis were 90.7%–108.2% and 1.1%–7.0%, at high, medium, and low quality control concentrations. Limits of quantification were 20 ng/mL for 3TC, 39.1 ng/mL for EFV, and 19.5 ng/mL for NVP and LPV.

Outcomes

Viral suppression on second-line ART was defined as a VL <400 copies/mL 2 weeks to 15 months following switch. Patients without VL results were excluded if they transferred to another program; otherwise they were considered to have failed treatment. *Alive in care* was defined as no record of leaving the program or loss to follow-up (ie, no contact for ≥ 6 months) by 15 months.

Exposures

Major DRMs were defined using the 2011 update of the International Antiviral Society–USA drug mutations list [29]. Cumulative DRMs were described in patients with >1 sample. *NRTI resistance at switch*, one of the key exposures of interest, was categorized as (1) none, (2) M184V/I, (3) 1–2 thymidine analogue mutations (TAMs) \pm M184V/I, and (4) NRTI cross-resistance mutations (≥ 3 TAMs and/or K65R and/or Q151M and/or T69ins) \pm M184V/I.

The second key exposure of interest was *nonadherence at switch*, as determined by subtherapeutic first-line drug concentrations with or without major DRMs. Therapeutic drug monitoring (TDM) guidelines recommend measuring trough drug

concentrations (C_{trough}) to evaluate efficacy of NNRTIs and PIs, with recommended thresholds for NVP, EFV, and LPV of ≥ 3 mg/L, ≥ 1 mg/L, and ≥ 1 mg/L, respectively [30]. In this study, we assumed that if ART was taken as prescribed, NNRTI and PI concentrations in untimed plasma samples should be greater than C_{trough} . Because 3TC plasma concentrations do not correlate well with the active intracellular metabolite, no TDM targets exist. Using data from pharmacokinetic studies of 3TC (300 mg once daily) in plasma, we calculated the population standard deviation and found the lower limit of the 95% confidence interval (CI) for C_{trough} to be approximately 20 ng/mL, the limit of quantification of the assay [31, 32]. Drug concentrations were defined as subtherapeutic if they were greater than C_{trough} (NNRTI and PI) or below the limit of quantification (BLQ) for the assay (3TC), and the regimen as subtherapeutic if either criterion was met. Finally, assuming that subtherapeutic drug concentrations and absence of major DRMs are markers of nonadherence, we categorized nonadherence at switch as therapeutic first-line ART vs subtherapeutic first-line ART plus major DRM vs subtherapeutic first-line ART with no major DRMs.

Patients were categorized to have *reported nonadherence on first-line ART* if, at any visit, the patient self-reported missing ART in the preceding 7 days and/or HCWs reported treatment interruptions for nonadherence. *Duration of viremia on first-line ART*, categorized as <12 and ≥ 12 months, was defined as the time between the first VL >400 copies/mL following viral suppression to date of switch, where all interim VLs were >400 copies/mL. Only the viremic period immediately preceding switch was considered. For patients without viral suppression on first-line ART, we assumed that (1) patients initiating first-line ART in-program were viremic from this date, and (2) patients transferring into care on ART were viremic for ≥ 12 months.

Statistical Analysis

Using risk ratios from modified Poisson regression with robust standard variance, we explored the association between the outcome VL <400 copies/mL on second-line ART and 2 key exposures, NRTI resistance at switch and nonadherence at switch [33]. Potential confounders were derived from prior analyses of this cohort and a literature review [5, 8, 34–36]. Confounders were added sequentially, starting with the variable leading to the greatest degree of confounding, and retained in the final model if they altered the effect size by $>10\%$. Analyses were undertaken using Stata software, version 11.

Ethical Approval

This study was approved by the research ethics committees of the University of KwaZulu Natal, the University of Cape Town, and the London School of Hygiene and Tropical Medicine. The Aurum Institute program database, maintained for monitoring and evaluation purposes, contained data collected as part of

routine clinical care. The workplace employers provided data on reasons for leaving the program through employers' records and hospital death registers. Dates of death were confirmed through program links with the National Death Register. The ethics committees waived the need for patient consent, as data were collected and samples stored as part of routine program practice, and all data, including resistance tests and drug concentrations, were both retrospective and anonymized.

Genbank Sequence Accession Numbers

KC921018-KC921144

RESULTS

Of 417 patients switched to second-line ART at a VL >400 copies/mL, 134 had available stored samples ($n = 29/205$ workplace and $n = 105/212$ community program). Genotyping was successful on 115 patients, of whom 8 had >1 sample genotyped (Figure 1). Nineteen patients were excluded because of sequence failure ($n = 9$), evidence of clustering on phylogenetic analysis ($n = 9$), or insufficient sample ($n = 1$). Eighty patients had sufficient samples for measuring drug concentrations.

The baseline characteristics of patients with and without samples are presented in Table 1 and Supplementary Table 1. One workplace program laboratory did not store samples; therefore, fewer samples were retrieved from this program. The differences in baseline characteristics between patients included and excluded from this study reflect this. The workplace program was predominantly male and the programs used different ART regimens.

On switching, the median age of patients was 36 years (interquartile range [IQR], 31–44 years), with a median duration on first-line ART of 545 days (IQR, 311–810 days); duration of viremia was 306 days (IQR, 118–547 days), CD4 count was 177 cells/ μL (IQR, 77–263 cells/ μL), and VL was 4.3 \log_{10} copies/mL (IQR, 3.8–4.7 \log_{10} copies/mL). Genotyping and/or drug concentrations were measured on samples taken a median of 28 days (IQR, 16–77 days; range 0–153 days) preceding switch. At venous sampling, ART comprised EFV (63.9% [$n = 78$]) or NVP (36.1% [$n = 44$]) with the NRTI backbone d4T/3TC (61.5%; $n = 75$), ZDV/3TC (36.1%; $n = 44$), TDF/3TC (1.6%; $n = 2$), or d4T/ddI (0.8%; $n = 1$). Six patients on ZDV and 2 on TDF had prior exposure to d4T.

Resistance and Drug Concentrations

Ninety-seven percent ($n = 112/115$) of patients genotyped were subtype C, 2 were subtype B, and 1 was subtype A. No major DRMs were detected in 23% ($n = 26$), ≥ 1 NNRTI mutations were found in 74% ($n = 85$), and ≥ 1 NRTI mutations were found in 70% ($n = 80$), of which M184V/I predominated (67%; $n = 77$). At least 1 TAM, K65R, or Q151M mutation was detected in 34% ($n = 39$), 3% ($n = 3$), and 3% ($n = 3$) of patients,

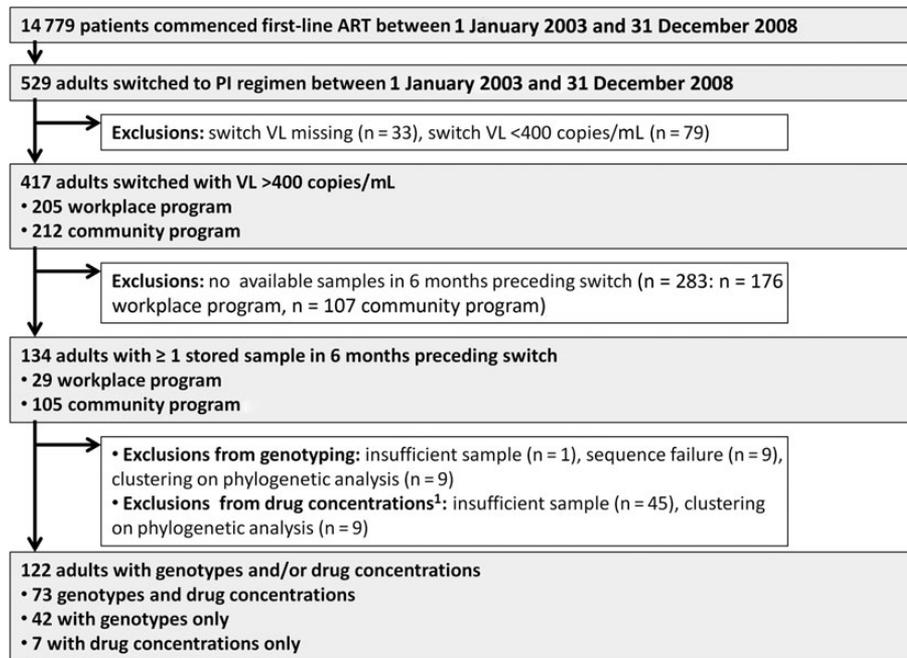

Figure 1. Study flow diagram. Selection of patients for analysis, from a cohort of patients initiating first-line, nonnucleoside reverse transcriptase inhibitor–based antiretroviral therapy between 1 January 2003 and 31 December 2008. Abbreviations: ART, antiretroviral therapy; PI, protease inhibitor; VL, viral load. ¹Patients with clustering on phylogenetic analysis were also excluded from having drug concentrations measured. One patient had insufficient sample to perform genotyping; however, after genotyping was performed, an additional 44 patients had insufficient samples available for measurement of drug concentrations.

respectively. Sixteen percent ($n = 19$) of patients harbored NRTI cross-resistance mutations.

Fifty-six percent ($n = 44/79$) of patients on 3TC had drug concentrations above the assay's limit of quantification (median, 613 mg/L [IQR, 170–1220 mg/L]; range, 25–1920 mg/L). Fifty-eight percent ($n = 19/33$) of patients on NVP had drug concentrations greater than C_{trough} : 8% ($n = 4$) 0.01–2.9 mg/L and 30% ($n = 10$) BLQ. Thirty-eight percent ($n = 18/47$) of patients on EFV had concentrations greater than C_{trough} : 25% ($n = 12$) <1 mg/L and 36% ($n = 17$) BLQ (Figure 2). The median drug concentration among patients with detectable NVP and EFV concentrations was 4.91 mg/L (IQR, 3.52–6.31 mg/L; range, 0.19–17.6 mg/L) and 1.47 mg/L (IQR, 0.4–2.8 mg/L; range, 0.02–27.6 mg/L), respectively.

Fifty-five percent ($n = 44/80$) of patients had subtherapeutic drug concentrations to at least one first-line drug: NNRTI and 3TC were BLQ in 24, NNRTI alone in 8 (NVP subtherapeutic, $n = 2$; EFV subtherapeutic; $n = 4$; EFV BLQ, $n = 2$) and 3TC alone in 11 (all BLQ). One patient whose NVP concentration was BLQ was not on 3TC-containing ART at time of sampling. Data on patients' self-reported adherence were available for one-third of patients at time of sampling ($n = 27/80$); 12 of 23 patients reporting adherence had subtherapeutic drug concentrations.

Seventy-three patients had drug concentrations and genotyping performed (Table 2). No major DRMs were detected in 3% ($n = 1/34$) of patients on therapeutic first-line ART vs 51% ($n = 20/39$) on subtherapeutic first-line ART ($P < .01$). Major DRMs were more likely to be detected in patients on therapeutic vs subtherapeutic first-line ART: NNRTI mutations in 94% vs 44%, M184V/I in 94% vs 26%, ≥ 1 TAMs in 47% vs 18% (all $P \leq 0.01$), and NRTI cross-resistance mutations in 26% vs 13% ($P = .23$), respectively.

Outcomes on Second-line ART

Eighty-three percent ($n = 101/122$) of patients were alive in care 15 months following switch to second-line ART (8 died, 7 were lost to follow-up, 4 transferred out, and 2 left for other reasons). There was no difference in retention for those with ≥ 1 NRTI mutations vs no NRTI mutations (82% [$n = 66/80$] vs 86% [$n = 30/35$]; $P = .67$) and those with therapeutic first-line ART preswitch with or without major DRM vs subtherapeutic ART plus major DRM vs subtherapeutic ART with no major DRM (82% [$n = 28/34$] vs 84% [$n = 16/19$] vs 75% [$n = 15/20$], respectively; $P = .8$).

Overall, 68% ($n = 83/122$) of patients achieved viral suppression on second-line ART. Five patients had no VL results: 4 died or were lost to follow-up and were considered to have

failed treatment, whereas 1 patient transferred to another program and was excluded from subsequent analyses. Patients with ≥1 NRTI mutations preswitch were more likely than those without to achieve a VL <400 copies/mL (78% [n = 62/79] vs 51% [n = 18/35]; *P* < .01). Patients on subtherapeutic first-line ART with no major DRMs were less likely to achieve viral suppression than those with major DRMs and those on therapeutic first-line ART (50% [n = 10/20] vs 74% [n = 14/19] vs 85% [n = 28/33], respectively; *P* = .03).

Association Between NRTI Resistance at Switch and Virological Outcomes

Unadjusted variables associated with viral suppression on second-line ART are presented in Table 3. The presence of NRTI resistance was associated with achieving viral suppression on second-line ART. This remained after adjusting for duration of viremia: cross-resistance DRMs (adjusted relative risk [aRR], 1.87 [95% CI, 1.08–1.71]) vs 1–2 TAMs (aRR, 1.79 [95% CI, 1.23–2.61]) vs M184V/I only (aRR, 1.61 [95% CI, 1.1–2.36]) vs no NRTI mutations (reference); n = 111; *P* = .02. Adjusting for drug concentration on first-line ART, magnitude of viremia, CD4 count, age, calendar year at switch, program, and transfers in on ART did not change the strength of association; these variables were not included in the final model (Table 3).

Association Between Nonadherence at Switch and Virological Outcomes

After adjusting for confounding due to duration of viremia and sex, patients on subtherapeutic first-line ART without major DRMs were least likely to achieve viral suppression, followed by those with subtherapeutic first-line ART and major DRMs, and finally those on therapeutic ART: subtherapeutic ART, no major DRM (aRR, 0.53 [95% CI, .32–.86]) vs subtherapeutic ART plus major DRM (aRR, 0.85 [95% CI, .6–1.2]) vs therapeutic ART with or without major DRM (reference); n = 70; *P* for trend = .01, *P* for departure from linear trend = .51.

First-line Antiretroviral Therapy Drug Concentration

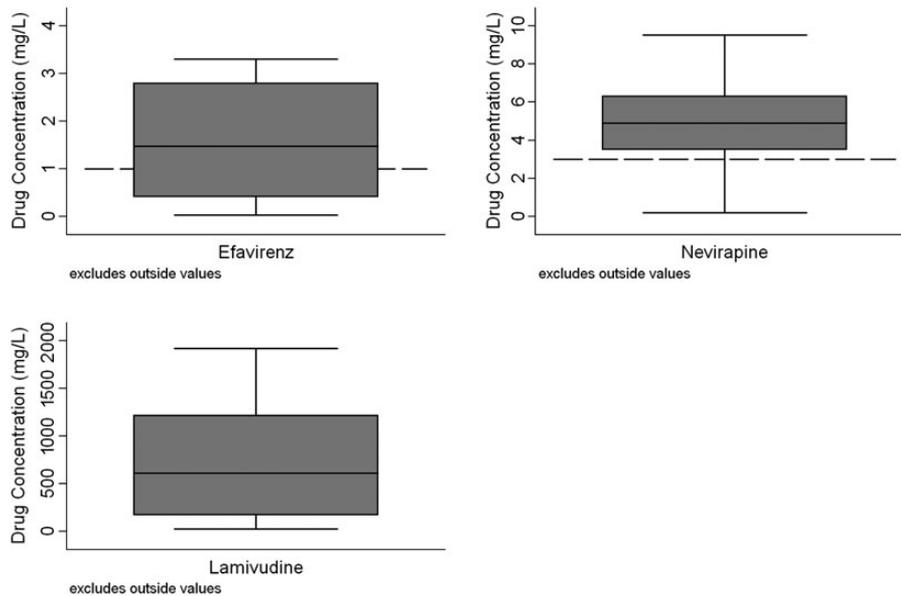

Figure 2. First-line antiretroviral therapy (ART) drug concentrations in stored plasma samples taken prior to switching to second-line ART. Included in this figure are patients with a drug concentration above the limit of quantification of the assay ($n = 30/47$ patients on efavirenz, $n = 23/33$ on nevirapine, and $n = 44/79$ on lamivudine). Excludes outside values: efavirenz, $n = 4$ (10.9 mg/L, 11.4 mg/L, 14.9 mg/L, 27.6 mg/L); nevirapine, $n = 3$ (10.6 mg/L, 11.4 mg/L, 17.6 mg/L); lamivudine, $n = 0$. For each box plot, the median value is denoted by the solid horizontal line; the inter-quartile range by the box; the upper and lower adjacent values by the whiskers; and C_{trough} by the dashed line.

Adjusting for magnitude of viremia, CD4 count, age, calendar year at switch, transfers in on ART, and program did not change the strength of association; these variables were not included in the final model.

Of the original cohort of 417 patients, 287 had a VL 12 months following switch to second-line ART, of whom 112 (39%) were >400 copies/mL. Fifteen of 16 samples located were successfully genotyped: 6 patients had no major DRMs, 8 had NNRTI mutations, and 5 had ≥ 1 NRTI mutation (M184V/I [$n = 3$], ≥ 1 TAM [$n = 2$], K65R [$n = 1$]). No major PI mutations were detected. Importantly, only 1 of 13 patients in whom drug concentrations were measured had LPV concentrations greater than C_{trough} .

DISCUSSION

This is the first study in a resource-limited setting to determine first-line ART drug concentrations among patients switching to second-line ART. The finding that 55% of patients had subtherapeutic drug concentrations on first-line ART, and that these patients were less likely to achieve viral suppression on second-line ART, suggests that efforts to intensify adherence support when switching regimens were often unsuccessful. Drug concentrations also influenced resistance patterns at switch; NRTI mutations were detected in 97% of patients on therapeutic first-line ART, compared to 31% on a subtherapeutic regimen.

However, rather than being associated with virological failure, the presence of NRTI mutations preswitch was associated with achieving viral suppression.

Previous cross-sectional studies of clinic cohorts, which included patients with virological suppression, found that 4%–16% of patients had drug concentrations greater than $<C_{\text{trough}}$; however, this is the first study in a resource-limited setting to measure drug concentrations at time of switch [37–39]. The high prevalence of subtherapeutic drug concentrations, at a time when adherence support should have been intensified, underlines the difficulties HCWs encounter in recognizing and successfully addressing nonadherence. Despite 55% of patients having subtherapeutic drug concentrations, nonadherence was the reported reason for switch in only 4%, lower than the 12% reported by Fox et al [5]. This suggests that HCWs failed to recognize and/or report ongoing nonadherence. The lack of pragmatic, valid measures of adherence makes assessing the success of adherence interventions difficult [21]. Certainly, in this study, patients' self-report proved unreliable, with more than half of the patients who reported full adherence having subtherapeutic drug concentrations. Strategies to improve adherence are not guaranteed, as they often require multidimensional, context-specific interventions [23, 40]. Murphy et al, in a South African clinic, found evidence of nonadherence, as measured by drug refill over the 6 months preceding switch, in one-third of patients

Table 2. Association Between Resistance and Drug Concentrations on First-line Antiretroviral Therapy (ART) in Samples Taken Prior to Switching to Second-line ART

Resistance Mutations	All (n = 73)	Therapeutic Drug Concentrations on First-line ART ^a (n = 34)	Subtherapeutic Drug Concentrations on First-line ART ^b (n = 39)	P Value ^c

Data are presented as No. (%).

Abbreviations: ART, antiretroviral therapy; DRM, drug resistance mutation; NNRTI, nonnucleoside reverse transcriptase inhibitor; NRTI, nucleoside reverse transcriptase inhibitor; TAM, thymidine analogue mutation.

^a Therapeutic first-line ART: NNRTI concentration equal to or greater than C_{trough} and lamivudine detected.

^b Subtherapeutic first-line ART: NNRTI concentration below C_{trough} and/or lamivudine below limit of quantification for the assay.

^c Fisher exact test.

[7]. Although this improved in the 6 months following switch, the effect was not sustained.

Overall, the pattern of DRMs observed in this study was consistent with others' findings: no major DRMs in 12% (23% in this study), NNRTIs in 86%–96% (74%), NRTIs in 81%–85% (70%), M184V/I in 68%–74% (67%), and NRTI cross-resistance mutations in 16% (16%) [6, 14, 16]. However, this study demonstrates how subtherapeutic drug concentrations influence resistance patterns. Nearly all patients on therapeutic ART had major DRMs detected, with 26% having NRTI cross-resistance mutations, which could impact on the long-term success of second-line ART. In contrast, half of patients on subtherapeutic first-line ART harbored no major DRMs and 13% harbored NRTI cross-resistance mutations. Although the absence of major DRMs may reflect a true absence due to short periods of nonadherence or very low adherence levels, treatment interruption may result in mutations being BLQ of the assay. For example, K65R, which is thought to emerge more readily in patients with subtype C virus [41], was detected in only 3 of 115 patients. K65R and M184V/I disappear rapidly (<4 months) after treatment interruptions, whereas TAMs, Q151M, and NNRTI mutations persist longer [17–19].

Although the majority of patients achieved early viral suppression on second-line ART (69% in this study vs 77% at 12 months in a meta-analysis [4]), failure to address patients' poor

adherence behavior at first-line virological failure, as indicated by subtherapeutic drug concentrations with/without major DRMs, placed them a high risk of failing second-line ART. Patients with subtherapeutic ART and major DRMs preswitch were more likely than those without DRM to achieve viral suppression, suggesting that the presence of major DRMs was acting as an indicator of better past adherence; to have acquired DRMs, patients must have adhered, if suboptimally, to ART. In our study, NRTI mutations did not have a detrimental effect on the activity of second-line ART but instead were associated with viral suppression. Others found no association [4, 16], perhaps due to the potency of PIs, short follow-up period, or small sample size. We believe the positive association found in our study suggests that NRTI mutations are acting as a marker of better past adherence.

Our study has several limitations. First, we have assumed that subtherapeutic drug concentrations are a marker of nonadherence; however, malabsorption or drug interactions may also contribute [42]. One of the commonest drug interactions occurs when both drugs are metabolized by CYP450 (eg, rifampicin and NNRTIs) [43, 44]. 3TC is not metabolized by CYP450 and should not be affected; in this study, 35 of 44 patients with subtherapeutic ART also had undetectable 3TC concentrations. Our definition may misclassify some nonadherent patients as being on therapeutic first-line ART, either because

^c All patients had major DRMs detected.

^d Test for trend (departure from linear trend $P > .5$).

of the untimed nature of the samples or a “white coat adherence” effect, whereby patients take their drugs before attending clinic, resulting in therapeutic drug concentrations despite recent poor adherence. On balance, we believe that subtherapeutic first-line ART (with or without major DRMs) provides a pragmatic, reasonably sensitive marker for nonadherence. Second, not all patients had switch samples, as only one laboratory routinely stored excess plasma and not all stored samples could be located. We do not believe the probability of samples being missing was related to our outcome; therefore, this should not have introduced bias. Third, we were unable to ascertain the respective contribution of resistance and subtherapeutic drug concentrations in all viremic patients on second-line ART. Of 417 patients switched to second-line ART, only 16 of 112 patients with VL >400 copies/mL 12 months following switch had samples available for analysis. The absence of PI mutations in the 15 patients successfully genotyped could be explained by a short follow-up period as PI mutations accumulate at a low rate [45]. However, the majority had low LPV concentrations, making it very likely that nonadherence was a major contributing factor [46–48]. Fourth, our sample size was relatively small, limiting the power to detect associations and assess confounding. Finally, these findings need to be confirmed in other settings. This cohort comprised a workplace- and community-based program. Compared to other programs, the workplace program has been shown to have higher levels of nonadherence and lower levels of viral suppression on first- and second-line ART; however, outcomes in the community-based program, which contributed 80% of this cohort, are comparable to other South African programs [8, 26, 49].

In conclusion, this study highlights that ongoing nonadherence is a major contributor to first-line virological failure when switching regimens and leads to suboptimal second-line outcomes. Patients need intensified adherence support when switching regimens if successful outcomes are to be realized; however, the optimal strategy for achieving this is unclear. In particular, HCWs need better guidance on how to manage patients with first-line virological failure who continue to be nonadherent, despite intensified support. At an individual level, switching nonadherent patients to a boosted PI-based regimen that is less susceptible to development of resistance may be appropriate and is the recommended strategy in many high-income settings. However, the cost-effectiveness of this approach for a public health program, where second- and third-line regimens are costly and treatment options limited, needs to be explored.

Supplementary Data

Supplementary materials are available at *The Journal of Infectious Diseases* online (<http://jid.oxfordjournals.org/>). Supplementary materials consist of data provided by the author that are published to benefit the reader. The posted materials are not copyedited. The contents of all supplementary data
