Bancroftian filariasis in an endemic area of Brazil: differences between genders during puberty

ABSTRACT
Gender differences in susceptibility to infectious diseases have been observed in various studies. A survey was performed in a bancroftian filariasis endemic area in the city of Olinda, Brazil. All residents aged 5 years or older were examined by thick blood film. People aged 9 to 16 years were interviewed and also tested for filarial antigenaemia. Data were analyzed by contingency table methods and regression models. The risk of microfilaraemia for males was significantly higher. Among those aged 9 to 16 years, the analysis of gender and filariasis by age showed that boys from 15 to 16 years had a higher risk of infection than girls. No association was found between menarche and filariasis in girls. The data suggest that variations between gender in filariasis could result, at least in part, from an increase in susceptibility of men. This epidemiologic feature needs to be considered while formulating elimination plans.

RESUMO
Diferenças entre os sexos quanto à susceptibilidade às doenças infecciosas têm sido observadas em vários estudos. Um inquérito de prevalência foi realizado em uma área endêmica de filariose bancroftiana na cidade de Olinda, Brasil. Todos os residentes com idade ≥ 5 anos foram examinados pela gota espessa. Moradores com idade entre 9 e 16 anos foram entrevistados e testados para a presença de antigenemia filarial. Os dados foram analisados utilizando tabelas de contingência e modelos de regressão. O risco de microfilaraemia nos homens foi significativamente mais elevado. Meninos com idade entre 15 e 16 anos tiveram maior risco de infecção filarial do que as meninas. Os dados sugerem que variações entre os sexos na filariose podem resultar de um aumento na susceptibilidade dos homens a partir da puberdade tardia. Essa característica epidemiológica deve ser considerada ao se formularem os planos de eliminação da endemia.

Gender differences in susceptibility to several diseases have been observed in a number of studies. In humans, epidemiological, laboratory and clinical studies have shown variations between gender in parasitic diseases including schistosomiasis, filariasis, leishmaniasis and onchocerciasis, as well as other infections such as rubella, measles, hepatitis B, and tuberculosis.

Filarial surveys carried out in Brazil and other endemic countries have observed a greater expression of infection and morbidity in males. Usually microfilaraemia and filarial antigenaemia, parasitic burdens and clinical manifestations are more frequently observed among males than females. Different levels of exposure to infected mosquitoes might explain these patterns. However, epidemiologic studies which investigated the influence of socioeconomic factors, occupational exposure, individual protection and type of clothing did not confirm their effect.

Differences between gender regarding the occurrence of diseases have also been related to physiological causes.
Logistic regression was used to test the association between gender and filarial infection (mf or CFA) adjusted for covariates. Finally, logistic regression models were constructed separately for boys and girls. EPI INFO (version 6.0) and STATA (version 6.0) were the statistical programs used.

The project was approved by the Ethical Committee of the Centro de Pesquisas Aggeu Magalhães/Fiocruz Foundation. All participants were informed about the objectives of the study and signed a consent form. Individual data and blood exams for participants under 18 years old were only performed after approval of a parent or guardian.

RESULTS

Epidemiological pattern of bancroftian filariasis in the whole population. Among 5,258 residents that took part in the parasitological survey, 328 (6.2%) were positive by thick film technique. There was a statistically significant association between sex and mf ($\chi^2 = 33.19; p < 0.0001$). The risk for males was significantly higher than the risk for females, even after adjustment by age group (adjusted OR = 1.94; 95% CI: 1.55-2.43; p<0.0001).

In males, the mf prevalence varied with age; it was 5.4% in the 5 to 9 age group, increased two-and-a-half times in the 15 to 19 age group, remained constant through the 20 to 29 age group and decreased to 4.7% by age 50. These differences were statistically significant ($\chi^2 = 29.99; p < 0.0001$) (Figure 1). Among females, the mf prevalence that was 3.9% in the 5 to 9 age group rose to 6.0% in the 15 to 19 group and then steadily decreased until reaching 2.8% in those over the age of 50. These differences in female age-specific prevalence were not statistically significant ($\chi^2 = 7.62; p = 0.267$) (Figure 1). The estimated mean microfilaraemic density of 1.63 (95% CI: 1.18-2.27) mf/60ml for males was significantly higher than the value of 0.45 (95% CI: 0.34-0.60) mf/60ml observed in females ($\chi^2 = 30.48; p < 0.0001$).

The mean microfilarial density in males was similar to that in females until the 10-14 age group, at which point male mean density increased sharply, peaking between the ages of 30 and 39 and decreasing from this point onward ($\chi^2 = 12.74; p = 0.04$). Among females, the mean microfilarial density remained relatively constant between 0.4 and 0.7 mf/60ml (Figure 1).

The risk for males was significantly higher than the risk for females, even after adjustment by age group (adjusted OR = 1.94; 95% CI: 1.55-2.43; p<0.0001).

In males, the mf prevalence varied with age; it was 5.4% in the 5 to 9 age group, increased two-and-a-half times in the 15 to 19 age group, remained constant through the 20 to 29 age group and decreased to 4.7% by age 50. These differences were statistically significant ($\chi^2 = 29.99; p < 0.0001$) (Figure 1). Among females, the mf prevalence that was 3.9% in the 5 to 9 age group rose to 6.0% in the 15 to 19 group and then steadily decreased until reaching 2.8% in those over the age of 50. These differences in female age-specific prevalence were not statistically significant ($\chi^2 = 7.62; p = 0.267$) (Figure 1). The estimated mean microfilaraemic density of 1.63 (95% CI: 1.18-2.27) mf/60ml for males was significantly higher than the value of 0.45 (95% CI: 0.34-0.60) mf/60ml observed in females ($\chi^2 = 30.48; p < 0.0001$).

The mean microfilarial density in males was similar to that in females until the 10-14 age group, at which point male mean density increased sharply, peaking between the ages of 30 and 39 and decreasing from this point onward ($\chi^2 = 12.74; p = 0.04$). Among females, the mean microfilarial density remained relatively constant between 0.4 and 0.7 mf/60ml (Figure 1).
stable through the 15-19 year age group, after which a slight decline was observed (χ² = 3.63; p = 0.726) (Figure 2).

**Relation between filarial infection, biological factors and bednet use in 9-16 year olds.** From the 1,511 boys and girls aged 9 to 16 registered in the area, 1,130 (72.7%) were interviewed and examined by thick film. Of those taking part, 790 (70%) were also tested for CFA by ICT card test (674) or Og4C3-ELISA (116). Those who were tested for CFA did not differ significantly from those who were not tested in age, sex or mf prevalence; this finding ensures the comparability of the two groups (data not shown).

The crude odds ratio (OR) for the association between mf and sex indicated a higher risk of mf among boys (OR = 1.60; 95% CI: 1.01-2.55) and CFA (OR = 1.76; 95% CI: 1.38-2.26) were similar to those obtained prior to adjustment. Bednet use was also tested as an effect modifier in the association between sex and mf, but the result was not statistically significant (χ² = 2.34; p = 0.12).

Due to the observed interaction between age and sex and also the fact that menarche only occurs in females, the association between filarial infection and co-variables was estimated separately for each sex. No association was found between menarche and mf (OR = 0.65; 95% CI: 0.16-2.68) or CFA (OR = 0.90; 95% CI: 0.31-2.63). Moreover, not using a bednet did not increase risk of mf (OR = 1.64; 95% CI: 0.56-4.81) or CFA (OR = 1.76; CI 95%:0.94-3.31) in girls. In boys, however, not using a bednet was associated with an increased risk of mf (OR = 6.24; 95% CI: 1.47-26.45) and CFA (2.66; 95% CI: 1.38-5.10). The presence of a microfilaraemic adult in the household was a risk of mf for both boys (OR = 3.10; CI 95%:1.46-6.50) and girls (OR = 3.57 95% CI: 1.56-8.15), but was not associated with CFA.

### DISCUSSION

In accordance with previous observations, this study showed a steady increase of both microfilaraemia and parasitic burden in males beginning at age 14. It is known that the sensitivity of thick film increases with higher microfilarial density. Since females usually exhibit lower parasite burdens than males, differential misclassification may underestimate the microfilarial prevalence in females and contribute to an apparent gender difference. In this study, analysis of the association between gender and filarial infection during puberty demonstrated that, although the prevalence of microfilaraemia was significantly higher in boys than in girls, this difference was not observed for filarial antigenaemia. This finding is consistent with the lower sensitivity of the thick film technique in females.

Assuming higher validity of the filarial antigenaemia results, the crude data do not suggest a gender difference in the 9-16 age range. Nevertheless, the stratified analysis by age showed a significantly higher risk of filarial infection in 15 to 16-year-old boys. The test for an age-sex interaction reinforced this finding that the effect of sex on filarial antigenaemia varies by age group. Therefore, it seems that changes in susceptibility to filarial infection might occur in men during the later stages of puberty. This phenomenon could be explained by the influence of either biological or behavioral factors acting in this period of life.

Culex quinquefasciatus is an endophilic mosquito of nocturnal habits that usually breeds in areas around dwellings. Although information concerning its biting behavior in Brazil is lacking, an entomological study in India found that the peak biting period of Culex ranged between midnight and 3 a.m. Considering this, different behavioral patterns between genders, such as current use of bednets, fans or insecticides while sleeping,
could be related to the differences between sexes in filarial infection. Nevertheless, the analysis of the association between sex and filarial infection during puberty suggests that, at least for microfilaraemia, the association between these variables occurred independently of the use of bednets and the presence of a microfilaraemic adult in the household. This result is in accordance with a previous epidemiological study carried out in a neighboring city, Recife, in which the filarial infection risk remained twice as high in men, even after adjusting for other exposure variables. Therefore, despite the difficulties of measuring human exposure to infection and in controlling for all the relevant behavioral factors, the data suggest that individual protection may not play a decisive role in the gender differences in lymphatic filariasis.

In girls, the occurrence of menarche, used as a proxy for increased estrogen production, was not protective against filarial infection. Moreover, age and non-use of bednet did not constitute increased estrogen production, was not protective against filarial female susceptibility to filarial infection. Changes, whether hormonal or behavioral, do not influence risks of infection for this sex. Moreover, age and non-use of bednet did not constitute increases in lymphatic filariasis. Protection may not play a decisive role in the gender differences in lymphatic filariasis.

Research has shown that men are often more susceptible to infections caused by parasites, fungi, bacteria and viruses. In addition, mortality rates are usually higher in males than in females. Paradoxically, the use of health services is less frequent in the male population. These social and biological particularities of genders have not been accounted for in the formulation of public health policies to prevent, control or eliminate diseases. For lymphatic filariasis, males not only exhibit more signs and symptoms of lymphatic damage, they also typically express more microfilaraemia and higher parasite burdens. These features characterize men as an important reservoir of filarial parasites that could maintain and spread disease in the community. Therefore, communication and educational approaches for elimination programs should focus on males by promoting their compliance with the mass chemotherapy for lymphatic filariasis and encouraging those with signs and symptoms to seek early diagnosis in order to prevent more severe forms of filariasis.

ACKNOWLEDGEMENTS

We thank to Professor Andre Furtado, Dr. Alexandre B. de Carvalho and Minister of Health of Olinda for the logistic support. Also thank to Fabio Brayner, Luiz Alves and Sergio Santos for their essential contribution during the fieldwork.
