Background: South Asian migrants show lower cancer incidence than their host population in England for most major cancers. We seek to study the ethnic differences in survival from cancer.

Methods: We described and modelled the effect of ethnicity, time, age and deprivation on survival for the five most incident cancers in each sex in South Asians in England between 1986 and 2004 using national cancer registry data. South Asian ethnicity was flagged using the validated name-recognition algorithm SANGRA (South Asian Names and Group Recognition Algorithm).

Results: We observed survival advantage in South Asians in earlier periods. This ethnic gap either remained constant or narrowed over time. By 2004, age-standardised net survival was comparable for all cancers except three in men, where South Asians had higher survival 5 years after diagnosis: colorectal (58.9% vs 53.6%), liver (15.0% vs 9.4%) and lung (15.9% vs 9.3%). Compared with non-South Asians, South Asians experienced a slower increase in breast and prostate cancer survival, both cancers associated with either a screening programme or an early diagnosis test. We did not find differential patterns in survival by deprivation between both ethnicities.

Conclusions: Considering recent survival trends, appropriate action is required to avoid deficits in cancer survival among South Asians in the near future.

People of Indian, Pakistani and Bangladeshi origin (South Asian) comprise the biggest minority ethnic group in the UK, constituting 4% of the total UK population, or half of all the non-European population in the UK (Office for National Statistics, 2003). South Asians mostly migrated to the UK in the 1950s and 1960s. The literature of cancer patterns in migrant populations refer to them as either South Asians or South Asian migrants, often without distinguishing between the first, second and the third generations. Patterns of cancer incidence, mortality and survival in South Asians in the UK have been shown to differ from the host population (Moles *et al*, 2007; Ali *et al*, 2010; Mangtani *et al*, 2010; Maringe *et al*, 2013). Incidence from the common cancers such as

breast, prostate, lung and colorectal are generally lower in South Asians, though the rates are steadily converging (Winter *et al*, 1999; Smith *et al*, 2003; Maringe *et al*, 2013).

Previous national and regional studies of breast cancer survival have shown higher survival for South Asians compared with the non-South Asian population, even though they tend to live in poorer areas (dos Santos Silva *et al*, 2003; Farooq and Coleman, 2005; Jack *et al*, 2009). Survival from oral (Warnakulasuriya *et al*, 1999; Moles *et al*, 2007) and cervical cancers (Bates *et al*, 2008) was higher among South Asian migrants compared with non-South Asians. By contrast, a regional study of cancer survival in children and young adults under 30 years of age showed that differences

between South Asians and non-South Asians vary with the type of tumour: South Asians had poorer survival from leukaemia and lymphoma compared with non-South Asians, but better outcomes from solid tumours (van Laar *et al*, 2012).

We sought to determine how cancer survival in the South Asian population of England has changed between 1986 and 2004, how it varies by age and deprivation, and how these patterns compare with those observed in non-South Asians. We used national cancer registry data, focusing on the five most common cancers in South Asians in the period 2000–2004 (Maringe *et al*, 2013): prostate, lung, colorectal, non-Hodgkin lymphoma (NHL) and liver in men, and breast, uterus, ovary, colorectal and NHL in women (index cancer). Deaths in older South Asians are not always well captured, possibly due to more frequent travel to South Asia once retired, which could compromise the estimation of the survival. We therefore limited the analysis to patients aged 15–69 years at diagnosis.

MATERIALS AND METHODS

Information on ethnic origin in the national cancer registry and population data were incomplete. Therefore, we applied the validated SANGRA (South Asian Names and Group Recognition Algorithm) algorithm (Maringe *et al*, 2013), after ethical and statutory approvals, to flag all South Asian patients in the national cancer registry, making use of their distinctive names. Despite already high sensitivity and specificity (Nanchahal *et al*, 2001) against self-assigned ethnicity (considered as the gold standard), we also visually inspected all names selected as South Asians to increase the specificity of the algorithm (Mangtani *et al*, 2010).

A total of 1 050 644 people were diagnosed in England between ages 15 and 69 years with an invasive, primary malignancy of interest. They were registered in the national cancer registry and followed up for their vital status until 31 December 2007. The quality of the data were assessed using standard criteria (Li *et al*, 2014), leaving 997 104 patients (94.9%) for analysis, among whom 13 979 (1.4%) were South Asians (Table 1). Proportions of exclusion varied widely across cancers and between ethnicities: overall 9.1% in South Asians and 5.0% in non-South Asians, but reaching 11.2%, 14.5% and 21.9% for NHL, lung and liver cancers in South Asians, respectively, that is, around 5–6% higher than in non-South Asians. South Asians were more likely than non-South Asians to be excluded because of unknown vital status (5.3% vs 0.9%), but the proportion of death-certificate-only registrations was generally similar or slightly higher among non-South Asians. Patients with no information on the postcode of residence at the time of diagnosis could not be assigned to an ecological deprivation score so they were also excluded (3058, 0.15%, similar for both ethnic groups).

Net survival, the metric of interest, is the survival that the cancer patients would experience after adjustment for death from other causes. Net survival is the only measure enabling comparison of cancer survival between populations experiencing different levels of mortality from other causes, as seen between South Asians and non-South Asians (e.g., for cardiovascular disease). In the absence of reliable information on the cause of death, net survival is estimated by comparing the overall mortality of the cancer patients with the mortality that would have been expected if they did not have cancer ('expected' or 'background' mortality), using a non-parametric estimator (Pohar Perme *et al*, 2012).

Expected mortality was derived from population life tables that we constructed by single year of age (0–99 years) and single calendar year (1986–2004), sex and deprivation category, for the entire population of England, as well as separately for the South Asian population. Ethnicity is not recorded at death, and death rates for South Asians were constructed by assigning ethnicity from the name in the national mortality database in the Office for National Statistics

(Mangtani *et al*, 2010), in the same way as for the cases in the national cancer registry. The number of deaths was taken as the mean annual number of deaths in the 3 years centred on the census year, to reduce the effect of random fluctuation. Populations were taken from the censuses for 1991 and 2001. Each small area was mapped to a deprivation index: the Carstairs index in 1991 (Carstairs, 1995) and the income domain of the Indices of Multiple Deprivation (IMD 2004) in 2001 (Department of the Environment Transport and the Regions, 2000), and aggregated into five categories by quintile of the national distribution. All-cause death rates per 100 000 per year by deprivation were then derived after aggregation of the number of deaths (numerator) and the population (denominator) by age, sex and ethnic group for each small area in England (Enumeration District in 1991, Lower Super Output Area in 2001) into the five deprivation categories. Linear interpolation was used to obtain a life table for each calendar year between 1991 and 2001. The 2001 life tables for South Asians and non-South Asians were assumed to apply over the years 2002–2004, and the 1991 life tables over the years 1986–1990. This enabled us to build a complete series of deprivation-specific life tables for South Asians and non-South Asians over the period 1986–2004. To our knowledge this is the first time that life tables specific for the South Asian population have been constructed in the UK (Cancer Research UK Cancer Survival Group, 2004).

For each cancer, we estimated net survival up to 5 years by ethnic group, age group and period of diagnosis (1986–1995, 1996–2004) using the Pohar Perme estimator (Pohar Perme *et al*, 2012) implemented in the STATA (StataCorp, 2013) command *stns* (Clerc-Urmès *et al*, 2014). Overall survival estimates were age standardised using the International Cancer Survival Standard weights (Corazziari *et al*, 2004).

Modelling the excess hazard of death enables investigating further the differences in net survival between South Asians and non-South Asians, and in particular, whether the effect of ethnicity varied with time since diagnosis, year of diagnosis, age at diagnosis and deprivation. The excess hazard of death (or excess mortality) is a measure of the mortality due to cancer over and above the expected mortality, defined earlier. In contrast with survival, a cumulative measure, the hazard is an instantaneous measure and therefore detects any changes in the rate at which excess or cancer-related deaths occur. We modelled the excess mortality on the log-cumulative excess hazard scale, using flexible functions (Nelson *et al*, 2007; Lambert and Royston, 2009). We allowed for non-linear effects of age and year of diagnosis by constructing restricted cubic splines for these variables, with knots located at the tertiles of the distributions. We also tested and allowed for time-dependent effects of ethnicity and other covariates. We used the log-likelihood ratio test to compare models with and without interactions between all co-variables and ethnicity, and with and without time-dependent effects of the interactions. All analyses were conducted using the *stpm2* command (Lambert and Royston, 2009) in STATA 13.

RESULTS

Patterns and trends in cancer survival. Age-standardised net survival was on average higher in South Asians than in non-South Asians, for most cancers. That contrast was stronger in 1986–1995 (Table 2). Survival was only lower in South Asians compared with non-South Asians for uterine cancer and NHL in 1986–1995. In 1996–2004, the survival advantage in South Asians was no longer seen for breast and prostate cancers especially at 5 years after diagnosis. The South Asian advantage in survival also considerably reduced between both periods for the other cancers. By 2004, survival was higher in South Asians compared with non-South Asians only for cancers of the colorectum (men), liver and lung.

^aDCO = death certificate only, these were case identified by death certificate or by autopsy only.

For example, in 1996–2004, 5-year colorectal cancer survival in men was 58.9% (95% CI 55.0–62.8) in South Asians and 53.6% (53.1–54.1) in non-South Asians. By contrast, 1-year survival from NHL in women was 73.7% (68.0–79.3) in South Asians and 80.5% (79.8–81.1) in non-South Asians in 1996–2004; this ethnic difference in survival has reduced over time.

The reduction in the gap in survival between South Asians and non-South Asians is a result of survival in non-South Asians increasing more rapidly than among South Asians between the early and late 1990s. This general pattern was not observed for the ovarian and uterine cancer; neither was it seen for NHL for which survival improved more rapidly among South Asians.

Only lung cancer patients aged 45–54 and 55–64 years at diagnosis, and NHL patients aged 65–69 years showed evidence of differences in survival between ethnic groups in the period 1996–2004 (Supplementary Table 1).

In 1986–1995, net survival from lung cancer in South Asian men was as high as 40.9% and 26.0% at 1 and 5 years, respectively, compared with only 26.3% and 8.5% in non-South Asians. In 1996–2004, 1- and 5-year survival in South Asians apparently declined by 6% and 10%, respectively, to reach 35.2% at 1 year and 15.9% at 5 years. By contrast, lung cancer survival among non-South Asians rose slightly, but was still lower than in South Asians (Table 2).

A very steep increase was observed in 5-year survival from prostate cancer in both ethnic groups: 20% in South Asians between 58.4% (43.3–73.5) and 78.4% (70.1–86.6) and a staggering

30% in non-South Asians between 51.0% (49.4–52.7) and 81.1% (80.1–82.2).

Patterns of changes in excess mortality. The excess hazard of death varied between ethnic groups for all cancers except ovarian and uterine cancers (*P*-values 0.13 and 0.15, respectively; Supplementary Table 2). We then tested whether the effect of ethnicity on the excess hazard changed with time since diagnosis, year and age of diagnosis and deprivation (Supplementary Table 2).

Excess cancer mortality among South Asians. South Asians experienced the usual patterns of high excess hazard in the first few months after diagnosis, followed by excess hazard close to zero at around 5 years after diagnosis (Figure 1). The excess hazard varied widely by age, and to a lesser extent by deprivation, in South Asians diagnosed with NHL, lung, liver and ovarian cancers. Excess hazard of dying in patients aged 65 years remained higher than patients aged 50 years until 5 years after diagnosis.

South Asians often experienced lower excess hazard of death than non-South Asians (lower part of Figure 1) in the 5 years that followed the cancer diagnosis. For cancers of the colorectum (women), lung (men) and prostate, South Asians had lower hazard of death from cancer throughout the first 5 years after diagnosis. That advantage in excess mortality widened with time since diagnosis for lung cancer, from a 15% lower mortality shortly after the diagnosis up to 75% at 5 years. On the other hand, in men, the excess hazard of death for colorectal and liver cancer became lower in South Asians only at least after 6 months since diagnosis, leading

Abbreviations: CI = confidence interval; NHL = non-Hodgkin lymphoma.

^aFor prostate cancer, it is not possible to compute the age-standardised 1-year survival for South Asians in the first period due to small number of patients in the youngest age group. Unstandardised survival figures are reported instead.

to 50% and 75% reduction at 5 years, respectively. For ovarian cancer, lower excess mortality was seen in South Asians only until 6 months after diagnosis.

By contrast, South Asians experienced a higher excess mortality than non-South Asians for NHL (EHR from 1.23 (1.07–1.42) and 1.39 (1.14–1.71) for men and women, respectively) and for cancers of the breast (EHR: 1.06 (1.00–1.12)) and the uterus (EHR: 1.14 (0.96–1.34)). This deficit in NHL survival vanished after 18 or 36 months since diagnosis for men and women, respectively.

Temporal trend in excess hazard of death by ethnicity. Among the few cancers for which the effect of ethnicity seemed to vary with year of diagnosis (Supplementary Table 2), 3-month and 1-year excess mortality from colorectum and liver cancer decreased rapidly in non-South Asians between 1986 and 2004, whereas it remained constant in South Asians, resulting in a reduced or null gap in excess mortality between both ethnic groups (Figure 2). Trends in 5-year excess mortality were less clear. For lung cancer (men), the trends in excess mortality at 3 months and 1 year diverged between ethnic groups, with a patent increase in South Asians and a slight decrease in non-South Asians: in 2004, excess hazards in non-South Asians were at 0.98 (0.96–1.00) and 0.67 (0.66–0.69) at 3 months and 1 year after diagnosis, respectively, similar to the excess hazards in South Asians (0.94 (0.84–1.05) and 0.55 (0.50–0.62) at 3 months and 1 year). The excess hazards for prostate cancer decreased much more quickly in non-South Asians than South Asians, at all times after diagnosis.

Age pattern in excess hazard of death by ethnicity. Excess mortality by ethnicity varied differently according to age at diagnosis for colorectal (women), NHL (men) and uterine cancer patients (Figure 3 and Supplementary Table 2). In South Asians, patients aged 15–35 years at diagnosis tended to die more from their colorectal cancer than the patients aged 50–69 years, while in non-South Asians, the age pattern was reversed, regardless of time since diagnosis. For the uterine cancer, a general U-shape of the excess mortality was observed for both ethnicities, but mirrored with the highest mortality among the younger patients for the non-South Asians and among the older patients for the South Asians: at 3 months after diagnosis, the excess hazards were 0.15 (95% CI 0.11–0.21) in South Asians aged 15 years and 0.17 (95% CI 0.13–0.23) in non-South Asians aged 69 years. For NHL male cancer patients, the increasing excess mortality with increasing age was much more marked in South Asians than among non-South Asians, especially 3 months after diagnosis.

Deprivation pattern in excess hazard of death by ethnicity. Deprivation patterns in South Asians were similar to that in non-South Asians for most cancers (Supplementary Table 2) with greater excess mortality in more deprived population. The trends in breast cancer excess mortality by deprivation was slightly steeper in South Asians than non-South Asians, while, for prostate cancer, the high excess mortality observed in non-South Asians shortly after the diagnosis was attenuated in South Asians for all deprivation categories (Figure 4). NHL cancer showed very

Figure 1. Excess hazard of death by age and deprivation in South Asians for patients diagnosed in 2004, and excess hazard ratios comparing South Asians to non-South Asians.

Figure 2. Change in excess hazard with year of diagnosis, by ethnic group at 3, 12 and 60 months after diagnosis, for cancers selected based on the significance of the interaction term year of diagnosis × ethnicity (patients aged 50, most affluent).

Figure 3. Change in excess hazard with age at diagnosis, by ethnic group at 3, 12 and 60 months after diagnosis, for cancers selected based on the significance of the interaction term age at diagnosis × ethnicity (2004, most affluent).

unstable excess hazard estimates by deprivation for South Asians, leading to a triangular relationship between excess mortality and deprivation: most probably, it was the reason for an interaction between ethnicity and deprivation.

DISCUSSION

This study aims at measuring trends in survival for the five most common cancers in each sex in South Asians living in England. To our knowledge, this is the first time survival from cancers other than breast cancer has been estimated for this ethnic group for the whole of England and over such a long period of time.

In the late 1980s, net survival in South Asians was either higher (colorectum, liver, lung and prostate) or similar to that in non-South Asians (breast, ovary, uterus and NHL). By 2004, however, the picture was very different: South Asians still experienced higher survival for lung cancer, but lower survival for NHL, while survival from other cancers had become similar in both ethnic groups. Adjusting for age at diagnosis and deprivation only resulted in small and inconsistent effects on the overall ethnic differences in survival.

We restricted our analysis to adults aged 15–69 years in order to avoid potential bias in the estimation of cancer incidence and survival among elderly South Asians. South Asians also tend to be diagnosed at younger ages than non-South Asians (Downing *et al*, 2011; Maringe *et al*, 2013).

The literature reports a mixed role for ethnicity and socio-economic background in cancer survival (Parikh-Patel *et al*, 2006;

Moles *et al*, 2007, Jack *et al*, 2009, National Cancer Intelligence Network, 2009, van Laar *et al*, 2012, Ortiz-Ortiz *et al*, 2014). Ethnic differences in 1- and 3-year age-standardised survival for cancers of the colorectum, breast (women) and prostate were reported to be minor, using HES-derived ethnicity (National Cancer Intelligence Network, 2009). It was also reported (National Cancer Intelligence Network, 2009), as we do here, higher lung cancer survival for Asian patients diagnosed between 2002 and 2006. Our study, however, presents methodological differences. To estimate the net survival for each ethnic group, we constructed separate life tables of background mortality for South Asians by single year of age, sex, deprivation category and calendar year (Cancer Research UK Cancer Survival Group, 2004; available on our website at publication). The survival models we employed included age at diagnosis, year of diagnosis and deprivation status. This approach provides the tightest possible control for differences and trends in background mortality by ethnicity and deprivation.

Name recognition remains the best way to identify persons of South Asian ethnicity when studying trends in population-based cancer survival in England, because self-assigned ethnicity is not routinely recorded at registration. Moreover, because some non-South Asian Muslim names could be confounded with common South Asian names, we have proceeded to additional checks of the South Asian names selected by the algorithm among cancer patients. The use of a name-recognition algorithm on cancer incidence data permits the inclusion of second and subsequent generations of migrants in the analyses, unlike using the country of birth as a proxy for ethnicity. Self-assignment of ethnicity, seen as the gold standard, is still incomplete in most health data sets

Figure 4. Change in excess hazard with deprivation, by ethnic group at 3, 12 and 60 months after diagnosis, for cancers selected based on the significance of the interaction term deprivation \times ethnicity (2004, most affluent).

(such as HES), which contain many records with two or more conflicting entries for the same patients. It has been advocated that despite their drawbacks, such data should be analysed anyway in order to drive up their quality (Aspinall and Jacobson, 2007). One study of the impact of self-assigned ethnicity on breast cancer outcomes in South Asians in the UK concluded that any technique (including imputation of missing ethnicity) used to identify the 'best' ethnicity led to very similar results (Downing *et al*, 2011).

Differences in cancer incidence and survival between Blacks and Whites (Bassett and Kreiger, 1986; Lannin *et al*, 1998; Breen *et al*, 1999) or within the Asian ethnic group (Pineda *et al*, 2001; Robbins *et al*, 2007, Bates *et al*, 2008; Gomez *et al*, 2010) have been reported in the US for decades, where ethnicity is sometimes used as a proxy for wealth (Ash and Robinson, 2009). In the US, where the South Asian population also comprises Japanese and Filipinos, their breast and prostate cancer survival is lower than in non-Hispanic whites (Robbins *et al*, 2007).

The hypothesis claiming that the ethnicity gap in survival widens with increasing amenability of cancer to treatment (expressed by increasing net survival) was tested in the US using SEER population-based data in the late nineties (Tehranifar *et al*, 2009). By amenability to treatment, we mean easy access to efficient treatment. Compared with the White population, the survival advantage initially found in Asian and Pacific Islanders (including South Asians) tended to disappear with increasing amenability, while deficit in survival observed in all other ethnic groups widened. Similarly, we found no significant difference between the survival experienced by South Asians and non-South Asians, during 1996–2004, for cancers with good survival and good amenability to treatment (prostate, uterine and breast cancers, 5-year survival higher than 70%) or for partly amenable cancers (NHL, ovary and colorectal cancer). The South Asian survival advantage remained over 5% higher in 'not amenable' cancers such as liver (at 5 years) and lung (at both 1 and 5 years). In the US, Asian ethnicity was identified as a favourable prognostic factor for overall survival from non-small cell lung cancer in California, even after adjustment for smoking status (Ou *et al*, 2009). We also found a significant advantage in lung cancer survival for South Asians, which matches the theory of minorities and amenability of cancers (Tehranifar *et al*, 2009). However, caution should be made in particular in the US where access to healthcare strongly depends on socioeconomic level (Desai *et al*, 2010).

Part of the temporal variations and ethnic differential in cancer survival may be due to data issues. For example, lung cancer survival in South Asians, very high in 1986–1994, decreased dramatically by 11% at 5 years. In 1986–1995, an extra 8% of South Asians compared with non-South Asians were excluded from the analysis, while the difference between both ethnic groups decreased to 3% in 1996–2004 (data available on request). Most of this difference was seen in the exclusion of cases due to unknown vital status, that is, patients could not be traced to assess their vital status. This could reflect a migration effect because of the South Asian patients returning to their home country to die (Pablos-Mendez, 1994, Scott and Timaeus, 2013). Restricting the age range to patients diagnosed between 15 and 69 years of age has reduced this effect, although the proportion of

unknown vital status was relatively constant in all age groups (data not shown). Furthermore, in order to evaluate whether the proportion of patients wrongly recorded as alive (also called 'immortals') at the time of the analysis differed by ethnicity, we calculated (on the full cohort) the proportions of patients who appeared to have survived beyond their 105th birthday by ethnicity: they were fairly similar. We also looked at the long-term survivors for bad prognosis cancers. For liver cancer, 5.7% of South Asians survived beyond 10 years (5.4% in ages 15–69) compared with 0.9% (0.7% in ages 15–69) in non-South Asians; for lung cancer, 9% (7.6% in ages 15–69) of South Asians and 1.7% (1.4% in ages 15–69) of non-South Asians. It suggests some differential losses to follow-up (death) by ethnicity.

During the study period, the widest changes in ethnicity-specific proportion of patients excluded were for liver, lung, and ovarian cancers and for NHL, whereas survival in South Asians either became worse than in non-South Asians (NHL) or dropped dramatically (lung). Except for liver cancer, the proportions of patients excluded in the most recent period were not greater than 3% of the cases. It suggests that the more recent comparisons in cancer survival between both ethnic groups can be considered as more reliable.

Screening uptake in South Asians was lower than in non-South Asians in 1996 (Szczepura *et al*, 2008), which might be reflected in the slower increase in 5-year survival from breast cancer in South Asians. Similarly, the situation for prostate cancer may be comparable with lower use of PSA (Melia *et al*, 2004). Policy on implementation of the mass screening programme for colorectal cancer (introduced since 2006) should account for differential screening uptake in South Asians. However, it should be noted that two-thirds of South Asian cancer patients belongs to the two most deprived groups. As screening uptake decreases with increasing deprivation, disentangling the role of ethnicity from that of deprivation remains challenging. Nevertheless, differential trends in survival between both ethnic groups could be partly due to the differential access to early diagnosis in the more recent years. Stage-specific survival was not performed because of lack of good quality information on tumour stage in the national cancer registry for the whole study period.

Cancer beliefs and attitudes vary between countries and, within a country, between ethnic groups (Forbes *et al*, 2011, 2013). South Asian women were found to have lower breast cancer awareness than White women (Forbes *et al*, 2011), while a qualitative study concluded that South Asian beliefs hindered their understanding of and access to breast cancer screening (Karbani *et al*, 2011). Younger generations, up to a third of the cancer patients in the most recent years of our study, may be more aware and receptive to public health messages but communications targeted to minority ethnic groups should still be used to reach newer generations and counteract misplaced beliefs. It is worth noticing that incidence of cervical cancer, although higher in South Asians than in non-South Asians, followed a similar downward trend in both ethnic groups (data not shown). That may reflect comparable trends in prevalence of risk factors and screening uptake. Two studies showed a survival advantage of South Asians for breast cancer in

the late 1980s and early 1990s (dos Santos Silva *et al*, 2003; Farooq and Coleman, 2005). Breast cancer survival in non-South Asians is now similar to that in South Asians, and encouraging self-examination and screening among South Asians should be a priority to maintain high South Asian survival.

Area-based deprivation measures were allocated to each cancer patient and split into five categories according to the quintiles of these deprivation measures in the English population. If this distribution remains fairly uniform in White patients, nearly two-thirds of the South Asian population and cancer patients fall into the two most deprived categories (data not shown). The deprivation gradient in cancer incidence was much less steep in South Asians than among non-South Asians (Maringe *et al*, 2013). By contrast, we found that deprivation gradient in cancer survival was generally similar in both ethnic groups. Socioeconomic inequalities in cancer survival did not decline following the implementation of the NHS Cancer Plan (Rachet *et al*, 2010), in particular as a consequence of a more rapid increase in survival among the more affluent cancer patients. Because of the skewed distribution towards more deprived categories of the South Asians, the slower survival increase in this population reported here could reflect more generally the experience of the most deprived groups in the population.

The more recent patterns of cancer survival in South Asians look rather similar to those for non-South Asians in England. The protective effect of South Asian ethnicity on cancer incidence and survival seems to have faded. This may be explained by the fact that, in addition to data quality issues, both the first and subsequent generations age and become more westernised. Majority of South Asian population, however, lives in most deprived areas while, in England, poorer cancer survival is largely driven by deprivation (Rachet *et al*, 2010). Deprivation is also associated with low screening uptake (von Wagner *et al*, 2009) and sub-optimal cancer management (Morris *et al*, 2008; Lejeune *et al*, 2010; Rachet *et al*, 2010). South Asians show slow increase in breast and prostate cancer survival; both cancers are associated with either a screening programme or a test for early stage disease. Without appropriate action, at least on deprivation-related factors, deficits in cancer survival may appear among South Asians in the near future.

ACKNOWLEDGEMENTS

CM participated in this research as part of the work of The Policy Research Unit in Cancer Awareness, Screening and Early Diagnosis. The Policy Research Unit in Cancer Awareness, Screening and Early Diagnosis receives funding for a research programme from the Department of Health Policy Research Programme. It is a collaboration between researchers from seven institutions (Queen Mary University of London, UCL, King's College London, London School of Hygiene and Tropical Medicine, Hull York Medical School, Durham University and Peninsula Medical School). This work was also partly based on preliminary work funded by a Cancer Research UK project grant (C23112/A2810, PI: PM). RL and BR were supported by the Cancer Research UK Cancer Survival Programme grant C1336/A11700.
