Genome-Wide Identification of Chlamydia trachomatis Antigens Associated with Trachomatous Trichiasis

Chunxue Lu,1,2 Martin J. Holland,3,4 Siqi Gong,1 Bo Peng,1,2 Robin L. Bailey,3 David W. Mabey,3 Yimou Wu,5 and Guangming Zhong1,2

PURPOSE. Chlamydia trachomatis is the leading infectious cause of blindness. The goal of the current study was to search for biomarkers associated with C. trachomatis-induced ocular pathologies.

METHODS. We used a whole genome scale proteome array to systematically profile antigen specificities of antibody responses to C. trachomatis infection in individuals from trachoma-endemic communities with or without end-stage trachoma (trichiasis) in The Gambia.

RESULTS. When 61 trichiasis patients were compared with their control counterparts for overall antibody reactivity with organisms of different chlamydial species, no statistically significant difference was found. Both groups developed significantly higher titers of antibodies against C. trachomatis ocular serovars A and B than ocular serovar C, genital serovar D, or Cblamydia pneumoniae antibodies were the highest. When antisera from 35 trichiasis and 26 control patients (with relatively high titers of antibodies to C. trachomatis ocular serovars) were reacted with 908 C. trachomatis proteins, 447 antigens were recognized by at least 1 of the 59 antisera, and 10 antigens by 50% or more antisera, the latter being designated as immunodominant antigens. More importantly, four antigens were preferentially recognized by the trichiasis group, with antigens CT414, CT667, and CT706 collectively reacting with 30% of trichiasis sera, whereas antigens CT442 reacted with 35% of normal and 19% of trichiasis antisera respectively.

CONCLUSIONS. The current study, by mapping immunodominant C. trachomatis antigens and identifying antigens associated with both ocular pathology and protection, has provided important information for further understanding chlamydial pathogenesis and the development of subunit vaccines. (Invest Ophthalmol Vis Sci. 2012;53:2551–2559) DOI:10.1167/iovs.11-9212

The obligate intracellular bacterium Chlamydia trachomatis is the leading cause of both infectious blinding diseases1 and sexually transmitted bacterial diseases2 worldwide. Repeated or persistent ocular infection with C. trachomatis can cause inflammatory pathologies in the eye, leading to trachoma, trachomatous trichiasis, and blindness. Despite extensive efforts in defining the role of host3–7 and bacterial factors8–11 in ocular inflammatory pathologies, chlamydial pathogenic mechanisms remain unclear. The main C. trachomatis serovars responsible for trachoma are A, B, and C, whereas C. trachomatis serovars D to L3 mainly cause urogenital tract infection.

To understand the molecular mechanisms of chlamydial pathogenesis and immunity in humans, efforts have been made to identify serological markers of Chlamydia-induced pathologies in either the female upper genital tract or ocular tissues. Antibodies to chlamydial heat shock protein 60 (HSP60) have been associated with Chlamydia-induced inflammatory damage in fallopian tubes,12–14 therefore the possibility arises that chlamydial HSP60 and host immune responses to HSP60 may contribute to chlamydial pathogenicity. There is evidence that shows that chlamydial HSP60 can directly activate macrophages to secrete inflammatory cytokines15 and that chlamydial HSP60 can also be the target of16,17 or promote16,18 T-cell responses; however, because of the high degree of amino acid sequence conservation between chlamydial and human HSP60 proteins, antibodies against chlamydial HSP60 may cross-react with host HSP60.19,20 A whole genome scale protein array profiling of antigen specificities of antibody responses to C. trachomatis urogenital infection has confirmed the association of HSP60 with tubal inflammatory damage and also identified new serological markers, such as OmcB, which are preferentially recognized by serum from patients with tubal factor infertility.21 A recent study also reported high titers of antibodies to C. trachomatis HSP60, chlamydial protease/proteasome-like activity factor (CPAF), and CT795 in Nepalese trachoma patients.9 In the current study, we compared the antigen specificity profiles of antibody responses to C. trachomatis in individuals with trichiasis and healthy controls from trachoma-endemic communities. This has revealed a map of the immunodominant C. trachomatis antigens in trachoma

and has identified antigens associated with both protection
and pathology in trichiasis.

MATERIALS AND METHODS

Ethical Permission and Study Participants

The study was conducted in accordance with the tenets of the
Declaration of Helsinki. The study and its procedures were approved
by the joint Gambian Government/Medical Research Council Ethics
Committee (SCCL2006.10 and 18). Informed consent was obtained
before the enrollment of each subject. Participants were recruited from
the Western, Central, and Lower River Regions of The Gambia between
May 2006 and February 2009. Trachoma was graded using the World
Health Organization simplified grading system by a single experienced
field supervisor. Subjects with trachomatous conjunctival scarring (TS)
who also had trichiasis (TT), defined as at least one eyelash touching
the globe of the eye, were identified. For each TT case, an age, sex,
and location–matched control subject with normal eyes who was not a
member of the same family was also recruited. Participants were age
matched within 5 years (up to 45 years of age) or 10 years (participants
older than 45 years). In a standardized manner, an ocular swab from
the everted tarsal conjunctiva of each participant was collected as
described previously.5,22 A venous blood sample was requested for the
isolation of peripheral blood mononuclear cells and plasma as
a final concentration of 5 mg/mL. Then, 10
8
from different countries on a dry ice cold chain.

Detection of Current C. trachomatis Ocular Infection

The AMPLICOR CT/NG test (Roche Diagnostics, Indianapolis, IN) was
used for detection of C. trachomatis in cases and controls as described
elsewhere.3 Positive and negative samples were assigned according to
the manufacturer's instructions. Sample quality, inhibition, and
sensitivity for PCR were assessed by PCR amplification of human
mitochondrial DNA–specific sequences as described previously.3

Cell Culture and Chlamydial Infection

HeLa cells (American Type Culture Collection, Manassas, VA) were
cultured in Dulbecco's modified Eagle's medium (DMEM; GIBCO PRL,
Rockville, MD) with 10% fetal calf serum (FCS; GIBCO BRL) at 37°C
with 5% CO2 as described previously.14,21,26 The C. trachomatis proteome array
was established based on the 908 open reading frames (ORFs) encoded by C. trachomatis
genital serovar D genome and plasmid.46 Bacterial lysates containing individual chlamydia-
genome-like fusion proteins were added to 96-well microplates precoated with glutathione (Pierce, Rockford, IL) at a 1:10 dilution in PBS
with a total volume of 200 μL/well. Lysates containing GST alone, as negative,
and GST-chlamydial protease/proteosomelike activity factor (CPAF), as positive controls, were also included on each plate. The plates were incubated overnight at 4°C to allow GST fusion proteins to bind to the plate-immobilized glutathione then blocked with 2.5% milk in PBS and washing with PBST (PBS with 0.05% Tween
20; Sigma-Aldrich). After blocking, human serum samples were
preabsorbed with bacterial lysates containing GST alone at 4°C
overnight, then incubated with glutathione beads (bioWorld, Dublin,
OH) for 1 hour at room temperature. This pretreatment can
significantly reduce background caused by non-specific human
antibodies. The human antibody reactivity was detected with a goat
anti-human-IgG, IgA, IgM conjugated with horseradish peroxidase
(HRP; Jackson ImmunoResearch Laboratories) plus the substrate 2,2'-
azino-bi(2-ethylbenzothiazoline-6-sulfonic acid) diaminonitroxyl
salt (ABTS; Sigma). The optical density (OD) was measured at 405 nm
using a microplate reader (Molecular Devices Corporation, Sunnyvale,
CA). To confirm the antibody binding specificity, all antisera were
further absorbed with lysates made from either HeLa cells alone or
C. trachomatis-infected HeLa cells before reacting with the fusion protein-coated plates. The antibody binding that remained positive after HeLa-
alone lysate absorption but significantly reduced by C. trachomatis-HeLa
lysate absorption was considered true positive. In addition, the fusion
protein-based array assay is also routinely evaluated using normal
human sera similarly preabsorbed as described previously for further
excluding nonspecific binding.14,20,26,30,31 In this particular experiment, we
used the proteome to assay sera from eight health individuals and
no significant binding was detected between any of the 908 fusion

The confluent HeLa cells were treated with DMEM containing 30
μg/mL of diethylaminomethyl (DEAE)-Dextran (Sigma, St. Louis, MO) for
10 minutes at 37°C. After removal of DEAE-Dextran solution, chlamydial
organisms were added to the wells for 2 hours at 37°C. The infected
cells were continuously cultured in DMEM with 10% FCS and 2 μl/ml
of cycloheximide (Sigma) for 30 (C. psittaci), 48 (C. trachomatis), or
72 (C. pneumoniae) hours before being processed for immunofluorescence assay as described in the following section. Infection was also
carried out in tissue culture flasks for preparing whole cell lysates.

Immunofluorescence Assay

Antichlamydial antibodies in human sera were titrated using an
immunofluorescence assay (IFA) as described previously.14,26,30 Briefly, Hela cells infected with different species and serovars of chlamydia
were fixed with 2% paraformaldehyde and permeabilized with 2% saponin. After blocking, human antisera was added to the chlamydia-
infected cell samples. The primary Ab binding was visualized with a
group of human IgG conjugated with Cy3 (red; Jackson Immuno-
Research Laboratories, West Grove, PA), and DNA was labeled with
eHoehst dye (blue; Sigma-Aldrich, St. Louis, MO). The highest dilution
of a serum that still gave a positive reactivity was defined as the titer of
the given serum sample. Serum samples were serially diluted and the
appropriate dilutions were repeated multiple times based on the
results obtained from prior dilutions to obtain a more accurate titer for
each serum. The slides were observed under an Olympus AX70
fluorescence microscope equipped with multiple filter sets (Olympus,
Melville, NY), as described previously.14,30

Chlamydial Fusion Protein-arrayed Microplate
Enzyme-linked Immunosorbent Assay

Glutathione S-transferase (GST) fusion protein enzyme-linked immu-
nosorbent assay (ELISA) for detecting human antibody recognition of
chlamydial proteins was carried out as described previously.14,21,26 The
C. trachomatis proteome array was established based on the 908 open
reading frames (ORFs) encode by C. trachomatis genital serovar D
genome and plasmid.46 Bacterial lysates containing individual chlamydia-
genome-like fusion proteins were added to 96-well microplates precoated with glutathione (Pierce, Rockford, IL) at a 1:10 dilution in PBS
with a total volume of 200 μL/well. Lysates containing GST alone, as negative,
and GST-chlamydial protease/proteosomelike activity factor (CPAF), as positive controls, were also included on each plate. The plates were incubated overnight at 4°C to allow GST fusion proteins to bind to the plate-immobilized glutathione then blocked with 2.5% milk in PBS and washing with PBST (PBS with 0.05% Tween
20; Sigma-Aldrich). After blocking, human serum samples were
preabsorbed with bacterial lysates containing GST alone at 4°C
overnight, then incubated with glutathione beads (bioWorld, Dublin,
OH) for 1 hour at room temperature. This pretreatment can
significantly reduce background caused by non-specific human
antibodies. The human antibody reactivity was detected with a goat
anti-human-IgG, IgA, IgM conjugated with horseradish peroxidase
(HRP; Jackson ImmunoResearch Laboratories) plus the substrate 2,2'-
azino-bi(2-ethylbenzothiazoline-6-sulfonic acid) diazonium salt
(Sigma). The optical density (OD) was measured at 405 nm
using a microplate reader (Molecular Devices Corporation, Sunnyvale,
CA). To confirm the antibody binding specificity, all antisera were
further absorbed with lysates made from either HeLa cells alone or
C. trachomatis-infected HeLa cells before reacting with the fusion protein-coated plates. The antibody binding that remained positive after HeLa-
alone lysate absorption but significantly reduced by C. trachomatis-HeLa
lysate absorption was considered true positive. In addition, the fusion
protein-based array assay is also routinely evaluated using normal
human sera similarly preabsorbed as described previously for further
excluding nonspecific binding.14,20,26,30,31 In this particular experiment, we
used the proteome to assay sera from eight health individuals and
no significant binding was detected between any of the 908 fusion
proteins and the normal human sera (data not shown). These eight sera displayed no significant reactivity with C. trachomatis-infected cells (data not shown).

Data Analyses

Data were analyzed using SPSS v. 15.0 software (IBM, Chicago, IL) as previously described. Student’s *t*-test was used to analyze the overall mean differences in anti-Chlamydia antibody titers between the two groups of patients or between different chlamydial species. Because prior analyses of antibodies against some or all Chlamydia species in trachoma patients showed no significant difference between case and control groups, a two-tailed test seems to be more appropriate for capturing all possible associations of antibody responses with a given group. Because the antibody titers had large variations within a given group, the serum titers were evaluated by ranges of less than 1:100 (Negative), 1:100 to 1:10,000 (Low), and greater than 1:10,000 (High). Chi-squared and Fisher’s exact test were used to compare overall antibodies to various chlamydial species and serovars.

For ELISA results, both Student’s *t*-test (for comparing quantitative OD value data reflecting reactivity intensity) and Fisher’s exact test (for comparing the number of anti-titers positively reacted with a given antigen as reactivity frequency) were performed. When Student’s *t*-test was used, the OD values after subtracting background from the same plate were used. When Fisher’s exact test was used, a response was determined positive when the OD value was equal to or greater than 2 SDs above the mean calculated from the same 96-well plate as previously described. We accepted that there would be some false-positive associations when screening antisera by the array and did not adjust *P*-values to account for multiple comparisons because the normal methods of correcting *P*-values and the general applicability of adjusting for multiplicity of tests remain contentious among biostatisticians. We did not estimate the power of the study because, in the absence of other proteome array studies with sera from trachoma endemic communities, it was not possible to estimate the size of the expected differences or the number of antigens that may be recognized. Unadjusted *P*-values after multiple testing are presented with the expected significant *P*-value level after Bonferroni correction presented in the footnotes. We calculated the potential number of false-positive reactive antigen-antisera reactions at the 5% level according to the method described by Stekel. At a *P*-value less than 0.05, the number of potential false-positive antigens reactive with sera is expected to be 0.05 × 19 = 1 when the 19 antigens listed Table 3 are analyzed statistically.

RESULTS

Patient Demographics

The study subject demographics information is listed in Table 1. Sixty-one case control pairs were screened against the different chlamydial species and serotypes used in the study (see Supplementary Material, available at: http://www.iovs.org/lookup/suppl/doi:10.1167/iovs.11–9212/-/DCSupplemental). Fifty-nine of these individual serum samples were then screened against the complete proteome array. Both groups had similar age, sex, and ethnicity distributions. Fifty-seven percent of the cases had TS/TT in both eyes. Overall, 10% of the cases had corneal opacity (CO) in at least one eye and phthisis (wasting) was observed in the left eye of a single individual who also had right eye TS/TT/CO. The ethnic groups from which the samples were collected were consistent with main ethnicities present in the Gambian districts and regions in which the study was performed. All ocular swabs for these samples were positive for human mitochondrial DNA. A single sample (L120) was positive by CT/NG Amplicor for current ocular infection with C. trachomatis. Tests for current infection with other ocular pathogens were not performed.

Both Trichiasis and Control Subjects Had High Levels of Antibodies to Ocular C. trachomatis but Not to Genital Serovars or C. psittaci Organisms

When antisera from 61 trichiasis subjects and 61 control counterparts were reacted with organisms from different chlamydial species, we found no statistically significant

Serum samples from Individuals with (61) or without (61) trichiasis were twofold serially diluted starting with 1:10 and reacted with HeLa cells infected with C. trachomatis, C. psittaci, or C. pneumoniae organisms. The highest dilution that still gave a positive reactivity was defined as the serum titer. Each serum sample was titrated in triplicate and the average was used as the geometric titer of a given serum sample. Student's \( t \)-test was used to analyze the differences between the two groups of patients. There was no statistically significant difference in titers of antibodies against any of the chlamydial organisms between the trichiasis and control groups. When the serum samples were divided into 3 categories (Negative, Low, and High) based on antibody titers, Fisher's Exact test showed no significance difference in any categories between the two groups.

Mapping Chlamydial Immunodominant Antigens in Individuals from a Trachoma-Endemic Area

Antisera from 59 individuals (33 trichiasis and 26 control sera) with the highest titers of antibodies to C. trachomatis ocular serovars were further reacted with 908 C. trachomatis proteins. As shown, a total of 447 C. trachomatis-encoded proteins were recognized by at least 1 of the 59 antisera (Figs. 1A, 1B, 1C and 1D). Of these sera, 50% or more serum samples (Fig. 1D). These 10 antigens were designated as immunodominant antigens. Interestingly, 5 of the 10 immunodominant antigens are chlamydial proteins known to be secreted into the host cell cytosol (CT858, pCT03, CT456, CT694, and CT089). CT858, also called CPAF, is a serine protease that is secreted into host cell cytosol via a secretion pathway for manipulating host signaling pathways. CT456, known as translocated actin-recruiting phosphoprotein (TARP), is an effector molecule that is secreted into host cell cytosol via a type III secretion pathway to facilitate internalization of chlamydial elementary bodies (EBs) by inducing actin polymerization. CT694 is also a type III secretion effector that modulates host cytoskeletal protein organization during EB invasion, whereas CT089 or CopN is a type III secretion pathway regulator. Among the remaining 5 immunodominant antigens, CT143 is a hypothetical protein (HP), whereas CT841 (FtsH) and CT806 (Ptr) are proteolytic enzymes. CT240 is a recombinase (RecR), whereas CT517 is the 50S ribosomal protein L24. Although many of these immunodominant antigens overlap with those recognized by patients who are urogenitally infected with C. trachomatis, the sera from those with ocular exposure appear to selectively recognize any of the chlamydial antigens against any of the chlamydial organisms. The differences in reactivity and preferentially recognized by individual groups (Table 4). A positive reaction between an
antigen and an antiserum was defined as a reaction with an OD value equal to or above the mean plus 2 SDs derived from the same microplate and used for calculating reactivity frequency for a given antigen. Both the reactivity intensity (expressed as absolute OD values) and reactivity frequency of an antigen were statistically compared between trachiasis and normal control groups. We found that sera from trichiasis patients preferentially recognized four antigens. Antigens CT414, CT667, and CT706 reacted with 30% of antisera from trichiasis but none from the normal group. Antigen CT695 reacted with 61% of trichiasis but only 31% of normal group antisera (Fig. 2). These four antigens were designated as pathology-associated antigens. CT414 is a polymorphic outer membrane protein designated as PmpC. CT667 is predicted to be a type III secretion effector with unknown function. CT706 is an ATP-dependent ClpP endopeptidase subunit. CT695 is a hypothetical protein encoded by an ORF downstream of CT694, a known type III secretion effector.

We also found that eight other antigens were preferentially recognized by the normal control subject group with antigens

The antibodies against different chlamydial organisms were compared against each other using ANOVA (data not shown) and Student’s t-test. The titers of anti-C. trachomatis serovar A or B antibodies in the 122 subjects are significantly higher than those of anti-C. trachomatis serovar C or D, suggesting that these 122 individuals were mainly infected with ocular serovars A and B. The titers of antibodies against C. psittaci are the lowest, whereas those of anti-C. pneumoniae antibodies were highest in the same 122 individuals, which both confirms that the titers of antibodies detected in the assay were not caused by cross-reactivity and indicates that most of the 122 individuals were also coinfected with C. pneumoniae but not C. psittaci.

61% of trichiasis but only 31% of normal group antisera (Fig. 2). These four antigens were designated as pathology-associated antigens. CT414 is a polymorphic outer membrane protein designated as PmpC. CT667 is predicted to be a type III secretion effector with unknown function. CT706 is an ATP-dependent ClpP endopeptidase subunit. CT695 is a hypothetical protein encoded by an ORF downstream of CT694, a known type III secretion effector.

We also found that eight other antigens were preferentially recognized by the normal control subject group with antigens

![Figure 1](http://iovs.arvojournals.org/pdfaccess.ashx?url=/data/journals/iovs/932979/ on 10/09/2017)

**Figure 1.** Reactivity of 33 trichiasis and 26 normal control antisera with 908 ORFs of C. trachomatis. Each of the human antibodies (displayed along the x-axis on top of each panel) after 1/1000 dilution was reacted with each of the 908 ORF GST fusion proteins (listed along the y-axis) immobilized onto the 96-well microplates. Each colored bar represents a positive reactivity between a given ORF and an antiserum from trichiasis (Tri, green) or normal control (Ctl, red) group. The results are expressed as OD readings obtained at the wavelength of 405 nm. Any reaction with an OD ≥ mean + 2 SDs calculated from the same plate is defined positive. The positive OD values are expressed as binding intensity in increasing brightness of fluorescent color. The negative OD values are black. The 908 proteins are listed first in order of the ORFs from CT001 to pCT08 (A). The 908 proteins were then reordered based on binding frequency by the trichiasis antiserum from high (top) to low (bottom; see [B]). As indicated on the right of the panel, a total of 447 ORFs were recognized by one or more antiserum. (C) By visual inspection of the expanded view of the positive antigens, the fusion proteins preferentially recognized by either trichiasis (green) or control (red) antisera were marked with brackets on the right of the panel. (D) A total of 10 antigens were recognized by 50% or more of the 59 antisera.
CT019, CT117, CT301, CT553, CT556, CT571, and CT709 reacting with 46% of antisera from normal but none from trichiasis groups, and CT442 reacting with 35% of the normal and 19% of the trichiasis antisera respectively. Most of these proteins (CT019 [isoleucyl-tRNA synthetase or ileS], CT301 [probable serine/threonine kinase or pknD], CT553 [FMU/SUN-related methyltransferase or fmu], CT709 [rod shape determining protein MREB/HSP70 sugar kinase or mreB]) are metabolic or modifying enzymes. CT117 and CT556 are hypothetical proteins. CT571 is related to the general secretion pathway (GspE), whereas CT442 is a cysteine-rich 15-kDa outer membrane protein.

**DISCUSSION**

In the current study, we have demonstrated that the overall antibody responses to chlamydial organisms are indistinguishable between individuals with or without trichiasis in trachoma-endemic communities. Most individuals developed high titers of antibodies against both *C. trachomatis* ocular serovars A and B and *C. pneumoniae* organisms regardless of the trichiasis status. It is likely that the antibodies detected using *C. trachomatis* ocular serovar A and B organisms are induced by ocular infection with *C. trachomatis* serovars A and B in the study subjects and are not as a result of cross-reactivity between *C. pneumoniae*-induced antibodies and *C. trachomatis* ocular organisms. This is because these individuals displayed significantly lower levels of antibodies to *C. trachomatis* ocular serovar C, genital serovar D, and *C. psittaci* organisms, although the *C. pneumoniae* genome is believed to share similar levels of homology with all *C. trachomatis* serovars and an even higher level of homology with *C. psittaci*. The observation that the antiocular serovar A and B antibody titers were significantly higher than that of antiseroserovar C antibodies suggests that *C. trachomatis* ocular serovars A and B were most prevalent in the communities from which our study subjects were recruited. This is in keeping with the results of previous studies in The Gambia, in which serovars A and B were found to be predominant.

To understand the molecular mechanisms of *C. trachomatis*-induced ocular pathologies and to identify biomarkers for trichiasis, we used a whole genome scale proteome array established based on the 908 ORFs encoded by *C. trachomatis* genital serovar D genome and plasmid to profile the antigen specificities of the anti-*C. trachomatis* ocular serovar antibodies in the study subjects. The *C. trachomatis* genital serovar and ocular serovar genomes are highly conserved. For example, there is 99.6% identity between serovars D and A. Major variations between the genital and ocular strain genomes are in the regions containing genes coding for tryptophan synthase A/B, cytotoxins, TARP and polymorphic membrane proteins or Pmps. In most cases, reported nucleic acid polymorphisms result in silent mutations or variations that lead to ocular serovar proteins with shorter sequences or loss of function. No ocular serovar–unique proteins have been identified. Thus, the genital serovar D proteins can be used to detect antibodies that recognize the vast majority of antigens from the ocular serovars. We recognize that the serovar D proteins-based proteome array has some limitations and would not detect antibodies that react only with ocular strain–specific epitopes; however, this deficiency should not significantly alter the major findings in the current study.

Among the 908 *C. trachomatis* proteins measured, 447 antigens were recognized by at least one of the human antisera and 10 antigens were recognized by 50% or more antisera, the latter thus designated as immunodominant antigens. Interestingly, 5 of the 10 immunodominant antigens are proteins known to be secreted into host cell cytoplasm, suggesting that chlamydial secretion proteins have enhanced immunogenicity. These immunodominant antigens have also

been shown to be preferentially recognized by individuals infected with *C. trachomatis* urogenital strains, suggesting that these proteins may be essential for *C. trachomatis* infection in humans, even though some of these proteins are not highly expressed in chlamydial EBs. Importantly, the proteome array has also allowed us to identify four antigens that were preferentially recognized by sera from the trichiasis group, thus these were designated as pathology-associated antigens. The four pathology-associated antigens are CT706, CT667, and CT414 reacted with 10 unique antisera from the trichiasis group (each marked with a star, representing 30% of the total trichiasis antisera) but failed to react with any normal control antisera (100% specificity), whereas the protection-associated antigens CT019, CT571, CT117, CT301, CT553, CT556, and CT709 reacted with 12 of the normal antisera (each unique antisera was marked with a star, representing 46% of the total control antisera) without reacting with any of the trichiasis antisera. However, the pathology-associated antigen CT695 and the protection-associated antigen CT414 reacted with both TT and NC antisera. Nevertheless, CT695 was statistically significantly recognized by TT whereas CT414 by NC respectively as revealed in Table 3.

Equally important, the same proteome array has also allowed us to identify eight antigens that were preferentially recognized by sera from the control group, thus designated as protection-associated antigens. The eight protection antigens are CT019, CT571, CT117, CT301, CT553, CT556, CT709, and CT709. Most of these proteins are highly conserved metabolic or modifying enzymes (CT019, CT301, CT553, CT709) or related to the general secretion pathway (CT571). The remaining three antigens are hypothetical proteins unique to *C. trachomatis*. CT117, consisting of 104 amino acids (aa) with a bilobal hydrophobic region and a pI of 8.21, is a putative inclusion membrane protein designated as IncF, and IncF is highly immunogenic in women urogenitally infected with *C. trachomatis*.

**Figure 2.** Distribution of the reactivity patterns of 12 *C. trachomatis* antigens with 59 patient antisera. Number of trichiasis (TT) and control (NC) antisera that positively (POS) reacted with each of the 12 antigens (listed at both top and bottom of the figure) is summarized in (A). The reactivity distribution patterns of the 12 antigens with 33 trichiasis and 26 control antisera are revealed in (B) and (C), respectively. Each horizontal bar indicates a positive reactivity. The pathology-associated antigens CT706, CT667, and CT414 reacted with 10 unique antisera from the trichiasis group (each marked with a star, representing 30% of the total trichiasis antisera) but failed to react with any normal control antisera (100% specificity), whereas the protection-associated antigens CT019, CT571, CT117, CT301, CT553, CT556, and CT709 reacted with 12 of the normal antisera (each unique antisera was marked with a star, representing 46% of the total control antisera) without reacting with any of the trichiasis antisera. However, the pathology-associated antigen CT695 and the protection-associated antigen CT414 reacted with both TT and NC antisera. Nevertheless, CT695 was statistically significantly recognized by TT whereas CT414 by NC respectively as revealed in Table 3.
C. trachomatis. \cite{2558} CT556, consisting of 159 aa with a putative transmembrane domain at its C-terminus and an acidic pI of 4.95, shares a low level of homology with a thiol-disulfide interchange protein DsbC of Pseudomonas aeruginosa. \cite{2558} CT4/42 has been characterized as a cysteine-rich 15-kDa outer membrane protein, designated as CrpA. \cite{2558} CT4/42 is predicted to localize in the inclusion membrane; moreover, it contains a murine CD8+ T-cell epitope that can elicit partial protective immunity to subsequent challenge with C. trachomatis. \cite{2558} These three antigens (CT117, 442, and 556) appear to be suitable candidates for vaccine development, as they possess properties ideal for constructing an antichlamydia subunit vaccine: each are \textit{C}hlamydia-specific, likely localized in chlamydial organism or inclusion membrane, immunogenic in humans, and able to induce protective immunity. More than half a century ago, vaccination with formalin-fixed whole chlamydial organisms not only failed to induce long-lasting protective immunity against trachoma but also exacerbated ocular pathologies when some immunized children were exposed to natural infection.\cite{2558,62} These early observations might suggest that the formalin-fixed organisms not only had their protective antigen conformation altered by formalin fixation but also carried pathogenic antigens. Thus, a subunit vaccine by selecting protective antigens in their native conformation and excluding the pathogenic determinants may represent a promising approach for development of a vaccine to prevent trachomatous disease. Further evaluation of a murine CD8+ T-cell epitope that can elicit partial protective immunity to subsequent challenge with C. trachomatis. \cite{2558} These three antigens (CT117, 442, and 556) appear to be suitable candidates for vaccine development, as they possess properties ideal for constructing an antichlamydia subunit vaccine: each are chlamydial-specific, likely localized in chlamydial organism or inclusion membrane, immunogenic in humans, and able to induce protective immunity. More than half a century ago, vaccination with formalin-fixed whole chlamydial organisms not only failed to induce long-lasting protective immunity against trachoma but also exacerbated ocular pathologies when some immunized children were exposed to natural infection.\cite{2558,62} These early observations might suggest that the formalin-fixed organisms not only had their protective antigen conformation altered by formalin fixation but also carried pathogenic antigens. Thus, a subunit vaccine by selecting protective antigens in their native conformation and excluding the pathogenic determinants may represent a promising approach for development of a vaccine to prevent trachomatous disease. Further evaluation of these \textit{C}hlamydia-specific protection-associated antigens for their ability to induce protective immunity in an appropriate model system should provide important information for developing a subunit vaccine against C. trachomatis ocular infection and C. trachomatis-induced ocular diseases.
