Institutional ageism in global health policy
Peter G Lloyd-Sherlock and colleagues argue that a focus on premature mortality is discriminating against the needs of a growing older population

Institutional ageism

Ageism is defined as: “a process of systematic stereotyping and discrimination against people because they are old.”

Institutional ageism differs from, but is related to, interpersonal ageism. It involves the inclusion of ageist principles in formal rules and procedures and in wider institutional cultures. It is characterised by language consistently depicting older people in negative terms.

Less research has been done on ageism than on other forms of discrimination, such as racism and sexism. Studies of institutional ageism have mainly explored discrimination in employment and the workplace, and few studies explicitly examine its role in health. Most of the health studies focus on specific groups, such as older people who are lesbian, gay, or bisexual or racial minorities.

Several arguments have been used to justify age discrimination in health policy. The “fair innings” argument posits that everyone is entitled to a certain quality adjusted life expectancy and so policies should prioritise interventions that deliver this, even if they often favour younger people. Accordingly, ageism may be fundamentally different to discrimination based on gender or race since it redresses existing disadvantage. Of course, there is the vexed question of how many years might be considered a “fair innings”: something that would require informed debate and social consensus among people of all ages before being adopted. More generally, these justifications for age discrimination contradict the universal principle of health as a fundamental right for all.

Other arguments for age discrimination draw on concepts of human capital and efficiency. These claim that older people make fewer contributions to society than younger adults and thus have less social and economic value. This links to stereotypes equating old age with frailty, weakness, and dependency, which are contradicted by evidence that many older adults make substantial economic and social contributions.

It is sometimes observed that older people’s health problems are relatively expensive to treat and that interventions generate few returns. Yet many conditions affecting older people can be treated cheaply, substantially extending healthy life expectancy.

Epidemiological roots of ageism: from YLLs to DALYs

Simple measures of overall mortality are skewed towards conditions that disproportionately kill older people, since most deaths occur in later life. This could unfairly underestimate conditions affecting younger age groups. To take account of this, the years of potential life lost (YLL) approach to measuring mortality was developed in the 1980s. YLLs weight the burden of mortality according to the number of years between the age at which death occurs and an arbitrary age threshold in later life, typically somewhere between 65 and 80. Averting the death of a person over that age is given a value of zero.

YLLs have been widely applied in research and health policy, with a range of threshold ages. However, they raise ethical and...
practical problems, including where to set the age threshold beyond which any added life years are deemed worthless. Although proponents of YLLs may not advocate that the value of survival beyond a certain age should literally be understood as worthless, the approach frames thinking in this ageist direction.

In 1993 the World Bank and WHO launched disability adjusted life years (DALYs) as a tool for studying patterns of disease and assessing health priorities. DALYs apply a disability weight to remaining years of life, up to a fixed YLL age threshold. Originally DALYs applied an additional weighting according to the age at which each year of life was lost: a year lost in childhood or old age was worth much less than for other ages. For example, the value given to a year lived at age 70 was less than half one at age 25. It was argued: “The young, and often the elderly, depend on the rest of society for physical, emotional and financial support. Given different roles and changing levels of dependency with age, it may be appropriate to consider valuing the time lived at a particular age unequally.” The only evidence used to justify age weighting was an “informal polling of tuberculosis programme managers,” and no evidence was produced to justify the strength of the age weights. Several studies noted that DALY age weighting and the Global Burden of Disease unfairly undervalued conditions mainly affecting older people. Yet age weighting continued in the Global Burden of Disease studies until 2010.

Global priorities and older people

By 1960 roughly half the global population aged 60 or over lived in low and middle income countries, rising to two thirds by 2015. Despite this shift, until the 1990s research and policy discussion about older people’s health took place almost exclusively in high income countries. There has been some growth in geriatric research and practice in low and middle income countries since, but global policy priorities have remained heavily focused on other issues, such as infectious disease and reproductive health. In the case of HIV/AIDS, WHO and UNAIDS supported the collection of prevalence data only for people aged over 50. By 2010, fewer than half UNAIDS national HIV progress reports included data on people aged over 50. This is already evidence that older people are also excluded from trials on reducing the risk of sexually transmitted diseases found by the earlier exclusion of older people from HIV targets. In 2008-13 Action Plan for the Prevention and Control of NCDs includes data on people aged over 50.

The potential effect on research and data collection is shown by the earlier exclusion of older people from HIV targets. In 2010, fewer than half UNAIDS national HIV progress reports included data on people aged over 50. A review of clinical trials on reducing the risk of sexually transmitted diseases found that over two thirds excluded people aged 50 or over. There is already evidence that older people are also excluded from studies of NCDs and from randomised controlled trials, making findings potentially inapplicable to them. A growing number of epidemiological studies apply the 70 and over categories. The challenges of reducing premature mortality from NCDs by a third are substantial, requiring a large reallocation of resources away from older people. Advocates of premature mortality argue that life interventions ultimately benefit people of all ages, but this approach excludes people currently aged 70 or over.

Use of the term premature mortality exacerbates and justifies existing age discrimination in healthcare by implying that survival after the age of 70 is fundamentally less important than survival at younger ages. It also distracts attention from major challenges that especially affect older people, including multimorbidity and palliative care.
Redressing the balance

Since the 1990s key aspects of health policy have been framed by ageist principles. The arguments used to justify age discrimination are evidently invalid. The prominent role given to premature mortality thresholds shows that ageism is becoming increasingly blatant. It is inconceivable that global targets would similarly discriminate against other groups, such as women or people with disabilities.

Engaging with ageism in health policy does not mean throwing the baby out with the bathwater. We still need mortality indicators such as YLLs, but they must be interpreted with care. Additionally, policy makers should explicitly assess how the choice of measure affects the priority given to each age group.

Highly cost effective health interventions exist for people of all ages. Improved surveillance increases the scope to capture the disease burden in older people. For example, promoting awareness and management of hypertension can substantially reduce preventable deaths and disability.\(^7\) In 2015 WHO published a major report on ageing and health,\(^8\) indicating that it is ready to jettison ageist concepts and champion a more ethical approach. Such progress must not be undermined by poorly considered global targets.

Contributors and sources: PL-S is lead author and guarantor. He produced a first draft of the paper. This received substantial inputs from all coauthors. The paper is based on published research and other publically available sources of information. All authors have participated in an informal campaign to alter the phrasing of SDG 3.4, which they view as explicitly ageist in its current form.

Competing interests: We have read and understood BMJ policy on competing interests, and have no relevant interests to declare.

Provenance and peer review: Not commissioned; externally peer reviewed.

Key messages

Despite growing numbers of people aged over 60 in low and middle income countries, health priorities remain focused elsewhere.

The target in the sustainable development goals to reduce premature mortality from non-communicable diseases reflects wider ageism in global health policy.

Policy makers should consider how the choice of measure affects the priority given to each age group.
