Submicroscopic *Plasmodium* prevalence in relation to malaria incidence in 20 villages in western Cambodia

Rupam Tripura1,2*, Thomas J. Peto1,3†, Christianne C. Veugen2, Chea Nguon4, Chan Davoeung5, Nicola James6, Mehul Dhorda1,7, Richard J. Maude1,3,8, Jureeporn Duanguppama1,9, Krittaya Patumrat1,9, Mallika Imwong1,9, Lorenz von Seidlein1,3, Martin P. Grobusch2, Nicholas J. White1,3 and Arjen M. Dondorp1,3

Abstract

**Background:** Cambodia has seen a marked reduction in the incidence of *Plasmodium falciparum* over the past decade without a corresponding decline in *Plasmodium vivax* incidence. It is unknown to what extent local transmission is sustained by a chain of clinical and sub-clinical infections or by continued re-introduction via migration. Using an ultrasensitive molecular technique, 20 villages in western Cambodia were surveyed to detect the low season prevalence of *P. falciparum* and *P. vivax* and local treatment records were reviewed.

**Methods:** During March to May 2015 cross-sectional surveys were conducted in 20 villages in Battambang, western Cambodia. Demographic and epidemiological data and venous blood samples were collected from 50 randomly selected adult volunteers in each village. Blood was tested for *Plasmodium* infections by rapid diagnostic test (RDT), microscopy and high volume (0.5 ml packed red blood cell) quantitative polymerase chain reaction (uPCR). Positive samples were analysed by nested PCR to determine the *Plasmodium* species. Malaria case records were collected from the Provincial Health Department and village malaria workers to determine incidence and migration status.

**Results:** Among the 1000 participants, 91 (9.1%) were positive for any *Plasmodium* infection by uPCR, seven (0.7%) by microscopy, and two (0.2%) by RDT. uPCR *P. falciparum* prevalence was 6.6%, *P. falciparum* 0.7%, and undetermined *Plasmodium* species 1.8%. Being male (adjusted OR 2.0; 95% CI 1.2–3.4); being a young adult <30 years (aOR 2.1; 95% CI 1.3–3.4); recent forest travel (aOR 2.8; 95% CI 1.6–4.8); and, a history of malaria (aOR 5.2; 95% CI 2.5–10.7) were independent risk factors for parasitaemia. Of the clinical malaria cases diagnosed by village malaria workers, 43.9% (297/634) and 38.4% (201/523) were among migrants in 2013 and in 2014, respectively. *Plasmodium vivax* prevalence determined by uPCR significantly correlated with vivax malaria incidences in both 2014 and 2015 (p = 0.001 and 0.002, respectively), whereas no relationship was observed in falciparum malaria (p = 0.36 and p = 0.59, respectively).

**Discussion:** There was heterogeneity in the malaria parasite reservoir between villages, and *Plasmodium* prevalence correlated with subsequent malaria incidence. The association was attributable chiefly to *P. vivax* infections, which were nine-fold more prevalent than *P. falciparum* infections. In the absence of a radical cure with 8-aminoquinolines, *P. vivax* transmission will continue even as *P. falciparum* prevalence declines. Migration was associated with over a third of incident cases of clinical malaria.

**Trial registration** clinicaltrials.gov (NCT01872702). Registered 4 June 2013

Background
Malaria incidence in Cambodia has decreased by approximately 42% from 2009 to 2015 [1]. The treatment records of the National Malaria Control Programme, which do not include the private sector, report that this was driven chiefly by a decline of 55% in Plasmodium falciparum, whereas Plasmodium vivax declined by only 17%. This progress was due to the roll-out of rapid diagnostic tests (RDTs), treatment of confirmed malaria cases with artemisinin combination therapy (ACT) provided by village malaria workers (VMWs), and the distribution of insecticide treated bed-nets (ITNs) [1].

The Thai-Cambodian border area around Pailin Province in western Cambodia has been a cradle of anti-malarial drug resistance. In the 1960s, resistance of P. falciparum to chloroquine emerged from this area before spreading to Asia and Africa and causing millions of deaths [2]. Since 2007 several studies have shown that P. falciparum in western Cambodia has become resistant to artemisinins and more recently to the partner drugs used in ACT, such as piperaquine [3–6]. Subsequently, artemisinin-resistant Plasmodium parasites were found on the Thai-Myanmar border and other parts of Southeast Asia [7]. ACT offers the most effective anti-malarial drugs currently available, and the loss of these drugs would be a setback of potentially disastrous proportions for global malaria control and for elimination strategies in Southeast Asia [8, 9]. There is increasing evidence that in order to prevent the spread of artemisinin-resistant P. falciparum it is necessary to completely interrupt P. falciparum transmission [10–12].

Previous surveys have described an asymptomatic reservoir of malaria in Cambodia [13, 14]. Microscopy and RDTs are not sensitive enough to detect the majority of sub-clinical Plasmodium infections [13, 15, 16]. High-volume, ultra-sensitive, quantitative polymerase chain reaction (uPCR) is a recently developed method that can detect approximately 85% of all sub-clinical Plasmodium parasitaemias and thus characterize in detail the micro-epidemiology of malaria in areas of low transmission. These sub-clinical parasitaemias may play an important role in the transmission of infection, especially in areas of low and seasonal transmission [17, 18].

There are large seasonal population movements in and out of Samlout District in Battambang Province where the study was conducted. People from the district, predominantly men, spend time working outside the district and some return infected with malaria parasites. Agricultural labourers from other provinces come into the district to work during harvests and may harbour sub-clinical malaria infections acquired in other parts of the country. Seasonal work in forests collecting fruit, vines and hunting small game puts local people at risk of infection. These may contribute disproportionately to the transmission of malaria parasites. Battambang Provincial Health Department reports that approximately 83% of all malaria cases were aged 15–49 years, and 82% were males in 2014. The proportion of malaria cases among migrant workers in Battambang increased from 19% in 2009 to around 40% in 2014. In Cambodian border areas, the role of local, national and international migrants in malaria transmission has been acknowledged; however, the attributable fraction of infections has not been determined [19]. Outdoor and forest-acquired malaria infections continue to be important sources of transmission despite high rates of deforestation in the border areas of Cambodia.

Accurate malaria risk stratification is important for targeting control and elimination activities. Following the decline in P. falciparum infections over the past decade in western Cambodia, it is unknown to what extent local transmission is sustained by a chain of clinical infections, a reservoir of sub-microscopic malaria, or by continued introduction via migration. 20 villages in western Cambodia were surveyed to detect the sub-clinical prevalence of Plasmodium infections in an area where transmission is low but persistent and analysed the data with reference to available treatment records.

Methods
Study site
During the low season of malaria in March to May 2015, cross-sectional surveys were conducted in 20 villages in Samlout District, Battambang Province, western Cambodia. All available VMW records and provincial malaria data were reviewed. Samlout District lies to the south of Pailin Province, north of Pursat Province and the Cardamom Mountains, and east of Thailand (Fig. 1). Samlout is primarily an agricultural district with forested areas along the border. Samlout was chosen for this study as it has villages with some of the highest incidence of clinical malaria in Battambang Province and seasonal transmission.

Selection of villages and participants
Within Samlout District, 18 villages with the highest malaria incidence in 2014 were selected along with
two neighbouring villages, totalling 20. A census based on pre-existing village population lists was updated and household lists were prepared. Surveyed households were selected using randomization methods from the list to ensure that every household had an equal chance of being selected. A stratified sampling method obtained approximately equal samples of adults aged 18 years or over from four groups (male/female, under/over 30 years). Unless the total number of households in a village was fewer than 50, no more than one person per household was selected. For the villages with fewer than 50 households, more than one participant was randomly selected from the list. In cases of refusal or a person being absent on the survey day, replacement participants were selected randomly from the same household or the next household on the list. Pregnant women were excluded from the randomization as they would be ineligible to join a mass anti-malarial treatment study which followed this survey.

Community engagement and informed consent
Public meetings were conducted in Khmer by a dedicated Community Engagement Team (CE-Team) to inform the commune authorities, VMWs and village leaders about the study. All residents were invited to a meeting prior to the survey where the consent form was read aloud and questions were answered. Individual written informed consent was obtained immediately prior to sample collection and interview. A fingerprint was obtained from participants who could not read and write and a witness countersigned their consent form.

Survey methods
Anthropometric and demographic data were collected, including tympanic temperature, height, weight, health status, malaria history, bed net use, travel history, and occupation; 1.5 ml of venous blood was collected in an EDTA tube. Samples were kept in a cool box and sent to a nearby hospital laboratory on the same day. If a
participant was febrile (defined as tympanic temperature \( \geq 37.5 \) °C) an RDT (SD BIOLINE Malaria Ag Pf/Pv, Standard Diagnostics, Inc, Gyeonggi-do, Republic of Korea) was performed immediately, and if positive, treatment was provided by the VMW according to national guidelines.

**Laboratory methods**

The samples were separated; 200 µl of whole blood was used to prepare a dried blood spot on filter paper, a blood smear for microscopy, and to perform haemoglobin assay (HemoCue® Hb 201+Analyzer SE-262 71 Angelholm, Sweden). Blood was tested for malaria by RDT and microscopy (asexual parasites/500 white blood cells (WBCs)). The remaining blood was centrifuged and plasma, buffy coat and 500 µl of packed red blood cells (pRBCs) for uPCR were separated into three different cryo-tubes and stored at −80 °C. Ten per cent negative controls of total participant samples were added for each village. All the samples were transported to the Mahidol University Faculty of Tropical Medicine molecular laboratory in Bangkok.

**Molecular laboratory procedures**

A detailed description, evaluation and validation of the high-volume ultrasensitive (uPCR) methodology has been reported previously [15]. In brief, batches of 500 µl of pRBCs were thawed and the DNA template, for detection and quantification of *Plasmodium* by PCR, was extracted and purified. An ultrasensitive quantitative real-time PCR method was used to detect the presence of malaria parasites and to estimate the numbers (genomes) of parasite per millilitre from each sample. The 18S rRNA-targeting primers and hydrolysis probes used in the assay have been validated and are highly specific for *Plasmodium* species. The lower limit of accurate quantitation of this method is 22 parasites/ml of whole blood [15].

A Quanti-Tect Multiplex PCR No ROX® (QIAGEN, Hilden, Germany) was used, and the PCR mixture and the cycling conditions were as per manufacturer’s instructions. For samples containing parasite DNA by uPCR analysis, *Plasmodium* species detection was attempted using real time PCR protocols specific to 18sRNA of *P. falciparum* and *P. vivax*. Samples for which *Plasmodium* species were not determined were reported as ‘unknown species’.

To detect polymorphisms associated with reduced susceptibility to artemisinin derivatives the open-reading frame of the PF3D7_1343700 kelch propeller domain was amplified using a nested PCR protocol [7]. Purified PCR products were sequenced at Macrogen, Republic of Korea and analysed using BioEdit version 7.1.3.0., using the 3D7 kelch13 sequence as reference (Accession: XM_001350122.1).

**Statistical analysis and data management**

Data were collected on case record forms and entered on smartphones before being exported into Open Clinica. Survey data were analysed by univariate and multivariate methods to identify risk factors for parasitaemia. Odds ratios with 95% confidence intervals were calculated to explore which variables were independently associated with subclinical infection. The Pearson Chi squared test was used to test for the significance of associations. Variables that were independently associated with sub-clinical parasitaemia at the level of \( p < 0.05 \) were explored by logistic regression to produce adjusted odds ratios. Incidence rate was calculated by dividing total malaria cases in a given year with the total village population and multiplied by 1,000. Malaria incidence and prevalence were compared by linear regression. The analysis was done in STATA 14.0 (Timberlake, USA).

**Additional data sources and clinical malaria incidence**

Malaria case reports were obtained from the Provincial Health Department and VMW records. Available treatment records were reviewed by cross-checking with the VMWs to confirm the identity of patients. The incidence of clinical malaria for 2014 and 2015 was compared to the prevalence of malaria parasites detected by uPCR in March and April 2015 for each village. Villages with no Health Department records were excluded from this comparison. For villages where only a hamlet (Chakriya: CKA, Samlaut: SLT, Kompoung Tuk A: KTA and Kompoung Tuk B: KTB) was selected for the prevalence survey, the incidence rate of the whole village population was used for the analyses. All prevalence survey participants were from registered households and were considered to be residents.

**Results**

**Description of the study population**

Population size and malaria incidence in 2014–2015 differed significantly among the 20 study villages. Population size ranged from 147 (in Ou Nounong: ONG) to 1012 (in Ouda: ODA). Malaria incidence per thousand ranged between two and 224 among villages in 2014 and 2-166 in 2015. Two villages (CKA, Miko: MKO) in 2014 and two villages (CKA, Peam: PEM) in 2015 were not listed in Provincial Health Department records, so no incidence data were available for these villages (Table 1). The median age of the study participants was 33 years (range from 18 to 78 years). The median age of male and female participants were 34 years (18–72 years) and 32.5 years (17–78 years), respectively; 11.7% (117/1000) subjects had a temperature
of 37.5 °C or higher; 65.4% (654/1000) had a history of malaria at any time prior to the survey.

Prevalence of \textit{Plasmodium} species by detection method
Among 1000 participants, 91 (9.1%) were positive for any \textit{Plasmodium} species by uPCR, seven (0.7%) by microscopy, and two (0.2%) by RDT. By uPCR, \textit{P. vivax} prevalence was 6.6% (66/1000), \textit{P. falciparum} 0.7% (7/1000), and 1.8% (18/1000) had undetermined \textit{Plasmodium} species. In Table 1 the parasite prevalence by uPCR is shown for each village.

The prevalence in the villages ranged from 0 to 30% by uPCR (test for heterogeneity \(p < 0.001\)). \textit{Plasmodium falciparum} parasites were detected by uPCR in four of the 20 villages, with \textit{P. falciparum} prevalence ranging from 2 to 6\% (\(p = 0.010\)). \textit{Plasmodium vivax} infections were detected by uPCR in 16 villages, with \textit{P. vivax} prevalence ranging between 2 and 26\%, (\(p < 0.0001\)) and the undetermined \textit{Plasmodium} species were detected in nine villages, prevalence ranging from 2 to 10\% (\(p = 0.011\) for heterogeneity). Three out of 20 villages with had no parasite prevalence by uPCR.

Factors associated with \textit{Plasmodium species} positivity by uPCR
Factors associated with any positive \textit{Plasmodium} species by uPCR are shown in Table 2. \textit{Plasmodium} species prevalence among males was 14.1\% (66/402) versus 4.7\% (25/532) among females \(p < 0.001\); 11.5\% (51/443) among those aged 18-29 versus 7.2\% (40/557) among those aged 30 or above \(p = 0.018\). \textit{Plasmodium} prevalence was 6.8\% (8/117) among those with temperature of 37.5 °C or higher versus 9.3\% (83/883) among those with a temperature below 37.5 °C (\(p = 0.365\)). Among participants with previous history of clinical malaria, 12.5\% (82/654) were parasitaemic versus 2.6\% (9/346) among those who said they had never had malaria (\(p < 0.0001\)).

Prevalence of \textit{Plasmodium} parasites among participants spending one or more nights in a forest within the same period was 22.4\% (35/156) versus 6.6\% (56/844) among those without any forest travel (\(p < 0.001\)). Among participants with parasitaemia, 27/91 (29.7\%) had recently stayed overnight in the forest in the same province, and 8/91 (8.8\%) had stayed in a forest in a different province; 56/91 (62\%) did not have a history of overnight...

*Incidence total malaria cases/total village population* 1000
*Prevalence total \textit{Plasmodium} species detected by uPCR/total number of test* 100

* Positive for \textit{Plasmodium} by high-volume qPCR, but the parasite genome count was too low for subsequent nested PCR to determine \textit{Plasmodium} species
stay in the forest (p < 0.001). Parasite prevalence among participants with a history of travel outside the village within the previous 3 months was 10.2% (25/245) versus 8.7% (66/755) among those without any travel history (p = 0.489). Among those with parasites, 66.7% (66/91) did not travel in comparison to 27.3% (25/91) who travelled outside the village. Among the 25 positives who travelled outside the village, 44% (11/25) had stayed overnight in the forest.

Prevalence of parasitaemia was 8.0% (68/849) among those who used ITNs every night, 15.2% (20/132) among those who sometimes used ITNs, and 15.8% (3/19) among those who never used ITNs, p = 0.004. Parasite prevalence varied between the strata used for sampling: 19.9% (39/196) among young men, 9.9% (27/272) among older men, 4.8% (12/247) among young women, and 4.6% (13/285) among older women. Men were more likely to use ITNs irregularly or never (27.1%; 127/468)
versus women (24.5%; 4/532) \( p < 0.0001 \). Men were also more likely than women to stay overnight in forests 28.4% (133/468) versus 4.3% (23/532), \( p < 0.0001 \). Young men (35.2%; 69/196) used ITNs irregularly or never, and 36.7% (72/196) had spent a night in a forest within the past 3 months.

After adjustment, being male (OR 2.0; 95% CI 1.2–3.5), younger adults (age 18–30; OR 2.1; 95% CI 1.3–3.4), recent forest travel (OR 2.6; 95% CI 1.5–4.5), and a prior history of malaria (OR 5.3; 95% CI 2.6–11.0) remained significantly associated with parasite prevalence.

Parasitaemia was higher among \( P. falciparum \)-positive individuals than those with \( P. vivax \). Parasitaemia was lowest among people with undetermined \( Plasmodium \) species where the species were not determined. Tympanic temperature was not associated with the level of parasitaemia for any \( Plasmodium \) species (Fig. 2).

Sub-clinical \( Plasmodium falciparum \)

Among participants with \( Plasmodium \) parasitaemia, seven/91 had \( P. falciparum \) parasites. Among the seven with \( P. falciparum \) parasites, ages ranged from 22 to 49 years. None reported fever within the 48 h before screening and none had a temperature \( >37.5 \, ^\circ\text{C} \). All reported having clinical malaria in the past, and five reported illness in the previous 48 h. Three came from one village, ODA, and two from another, Ou Ta Teak (OTK). Four had stayed in a local forest overnight in the previous 3 months, of whom two reported travel outside the village in the same period. Two were positive both by RDT and by microscopy. Only one of seven falciparum positives had a history of travel to another province within the previous 3 months. Five reported everyday ITN use.

Markers of artemisinin resistance

Six of seven \( P. falciparum \) parasite strains detected by uPCR could be sequenced for \( PfKelch \) 13 mutations. All six \( P. falciparum \) isolates obtained \( Pfkelch13 \) C580Y mutation.

Association between sub-clinical prevalence and clinical malaria incidence

Malaria incidence was obtained for 19/20 survey locations from provincial health department records in 2014 and 2015. Overall malaria prevalence in the March–April 2015 survey measured by uPCR significantly correlated with the incidence in each of 2014 and 2015 (\( p = 0.003 \) and \( p < 0.001 \), respectively. \( Plasmodium vivax \) prevalence correlated with \( P. vivax \) incidence (\( p = 0.001 \) and \( p = 0.002 \)), respectively. No correlation was observed between \( P. falciparum \) prevalence and incidence (\( p = 0.36 \) and \( p = 0.59 \)). The combined prevalence of \( P. vivax \) and undetermined \( Plasmodium \) parasites (\( p < 0.001 \)) was also correlated with \( P. vivax \) incidence. This was done as previous surveys found approximately 90% of undetermined \( Plasmodium \) species detected by uPCR in western Cambodia were later identified as \( P. vivax \) during 12 months of prospective follow-up (Additional file 1: Figure S1) [14] (Figs. 3, 4).

Village malaria worker treatment records

Among all clinical malaria cases reported by VMWs, 154 (12.7%) were among people aged 45 years and above, 842 (69.6%) aged 15–45, 189 (15.6%) aged five to 15, and (2.1%) aged <5 years. People recorded as migrants (no permanent address in the village) accounted for (297/634) 43.9% of all malaria cases in 2013, and (201/523) 38.4% in 2014; 914/1,210 (75.5%) of subjects were male and 295/1,210 (24.5%) were female. There was an approximately three-fold reduction in the number of \( P. falciparum \) and mixed \( P. falciparum \) and \( P. vivax \) cases from 88 (13.9%) and 237 (37.4%) in 2013, to 36 (7.3%) and 66 (13.0%) in 2014, respectively. The number and proportion of \( P. vivax \) cases increased from 309 (48.7%) in 2013 to 417 (79.7%) in 2014 respectively (Fig. 5).

Discussion

Spatial heterogeneity and risk factors for parasitaemia

Variations observed in the prevalence of malaria in the study villages were consistent with a recent study in the northeast of Cambodia, which also found evidence of heterogeneity of malaria prevalence in nearby villages.

In the low season nearly one in ten people had malaria parasites. Sub-clinical vivax parasitaemia had a higher prevalence than sub-clinical falciparum parasitaemia. The predominance of \( P. vivax \) in the infections detected in the survey is consistent with local treatment records.
A significant proportion of clinical falciparum cases were among migrants. More detailed information on travel history and places of overnight stay in malaria-endemic areas would be helpful to better explain where malaria infections were acquired.

Young men were at greater risk of clinical malaria and had a higher prevalence of sub-microscopic malaria parasites compared to older men or to adult women. Young men were also more likely to spend time in forests and use ITNs irregularly or not at all, consistent with other studies in Cambodia [20, 21].

*Plasmodium vivax* prevalence determined by uPCR significantly correlated with vivax malaria incidence in each of 2014 and 2015, whereas no relationship was observed for *P. falciparum*. Due to the shorter duration of *P. falciparum* infections, it is unlikely that a single snapshot of *P. falciparum* by uPCR during the dry season would be able to describe the picture of *P. falciparum* infections throughout the whole year. Whereas for *P. vivax*, the higher persistence of sub-clinical infections means a survey in the dry season reveals a large reservoir of infections. In a previous longitudinal study a large proportion of sub-clinical *P. vivax* persisted through the year and seasonality had little effect on the number of detectable infections [14]. Even with testing a relatively small sample of each village’s population, there was a

![Graphs](image-url)
significant association between numbers with clinical and sub-clinical *P. vivax*.

**Implications for vivax treatment**

There was a significant association between a prior history of malaria and having vivax parasitaemia. These self-reported histories (which often dated back many years) are not a promising target to guide screening or treatment as the absolute risk difference was 3% (12 versus 9% overall) and two-thirds of all participants reported a history of clinical malaria. However, clinical treatment records of confirmed malaria diagnoses are a more reliable predictor of persistent vivax parasitaemia [22].

**Implications for falciparum elimination**

To accelerate malaria elimination, malaria control programmes in Cambodia and other countries are evaluating various strategies for mass drug administration (MDA) [11, 23–25]. Although in the dry season *P. falciparum* prevalence in these villages was very low, six of seven uPCR-positive *P. falciparum* infections did not have recent history of travel to another province, suggesting some ongoing local transmission. Without the contribution of migrants to the clinical malaria records Samlout District may be close to interruption of *P. falciparum* transmission, but imported cases may undermine elimination. In a recent study in neighbouring Pailin Province,
a high proportion of *P. falciparum* clinical cases were found to have C580Y Kelch mutations, and in 2013-14 prevalence surveys in Pailin, approximately half of all asymptomatic *P. falciparum* infections had markers associated with artemisinin resistance [7, 14]. In Laos, a high proportion of asymptomatic parasitaemias had the same marker associated with artemisinin resistance [26].

**Limitations and strengths**

The cross-sectional survey design was unable to resolve whether past clinical malaria left persistent parasites or whether these individuals were parasitaemic because they were generally at a higher risk. This study was conducted during the dry season and studies from Pailin in 2013–2014 reported a several-fold variation in *P. falciparum* prevalence over one year; therefore, it is not possible to estimate the overall contribution of these infections to transmission in these communities. It was also not possible to determine the *Plasmodium* species of some parasitaemias. Generally these were the participants with the lowest quantity of parasite DNA. The incidence data could be incomplete as VMW data from 2014 may have missed some people who went to other places for diagnosis and treatment.

**Conclusions**

The low season reservoir consisted chiefly of *P. vivax* infections with very low *P. falciparum* prevalence. *Plasmodium vivax* prevalence correlated with incidence of clinical malaria episodes while *P. falciparum* did not. Knowledge of the crude *P. falciparum* incidence alone was not a reliable tool to predict the hidden parasite reservoir during the dry season in this instance. More detailed knowledge of the characteristics of the *P. falciparum* cases, such as occupation and travel history could potentially distinguish indigenous and imported malaria and thereby improve the use of local treatment records to predict the sub-clinical *P. falciparum* reservoir. This can be a particularly useful tool to target malaria elimination activities such as mass screening and treatment or mass anti-malarial drug administration.

Much clinical *P. falciparum* was among migrants, forest workers or those recently returned from other provinces, suggesting transmission inside the villages themselves is now very low. Young men were more likely to have sub-microscopic malaria than older men or females of any age and to exhibit behaviour that exposes them to the risk of infection (and transmission). Imported malaria has the potential to undermine provincial *P. falciparum* elimination efforts as clinical and sub-clinical infections are brought into the district by migrant workers and by local people returning from other provinces.

The spatial heterogeneity of *Plasmodium* prevalence between neighbouring villages shows that there is important variability in malaria epidemiology at a local level. Knowledge of the recent, detailed travel history of clinical malaria cases could provide crucial information about
the probable source of infection and could help determine the risk of infection within individual villages. Even in villages with indigenous transmission, strategies to screen or treat sub-microscopic malaria in the dry season may be undermined by subsequent immigration of parasitaemic individuals. Therefore, targeting high-risk groups, e.g., migrant labourers, forest goers, by offering free screening and treatment, may prevent re-importation of malaria parasites from areas of higher transmission to areas in pre-elimination state and this could be an effective tool to eliminate falciparum malaria. Simultaneously, mass treatment in high transmission areas around the start of the malaria transmission season at community level may reduce the incidence of falciparum malaria significantly. It could have a collateral effect on a whole geographical area moving towards malaria elimination.

Additional file

Additional file 1: Figure S1. Malaria prevalence by uPCR and incidence per 1000 in 2015 in 16 villages.

Abbreviations

ACT: artesinin-based combination therapy; DHA-PPQ: dihydroartemisinin-piperaquine phosphate; EDTA: ethylenediaminetetraacetic acid; ITNs: insecticide-treated bed nets; MDA: mass drug administration; nested PCR: nested polymerase chain reaction; uPCR: ultrasensitive polymerase chain reaction; VMWs: village malaria workers.

Authors’ contributions

RT, TP, NJ, and CV conducted the study. LvS, CD and CN supervised the study. AE and NW conceived of the study and provided scientific oversight. ML, JD, KP, and MD supervised the samples and molecular laboratory. TP, RT and RM analysed the data. RT, CV, TP, and LvS wrote the manuscript. All authors read and approved the final manuscript.
