SUMMARY. The main objectives of this study were to define the occurrence and levels of hepatitis B virus (HBV) DNA in asymptomatic HBV carriers, cirrhosis patients and hepatocellular carcinoma (HCC) cases from The Gambia, and to evaluate the risk for cirrhosis or HCC associated with HBV viremia. We used sensitive real-time quantitative PCR assays to measure HBV DNA in samples from a case–control study consisting of 60 asymptomatic HBV carriers, 53 cirrhotic patients and 129 HCC cases. Logistic regression was used to estimate the risks of cirrhosis and HCC associated with HBV-DNA levels and HBV e antigenemia (HBeAg) detection (a surrogate marker for viral replication). Detectable HBV viremia and HBeAg positivity were both significantly associated with cirrhosis (increasing risk by fourfold and 11-fold respectively) and with HCC (increasing risk by sixfold and threefold respectively). HBV-DNA levels were significantly higher in both HCC cases and cirrhotic patients compared to asymptomatic carriers (P < 0.01 for both). High-level HBV DNA (>10 000 copies/mL) was strongly associated with both HCC and cirrhosis (17- and 39-fold increased risk). Lower level HBV viremia (200–10 000 copies/mL) conferred a significant risk of HCC, although the association with cirrhosis was not significant. In conclusion, we find that high HBV-DNA levels are strongly associated with the serious sequelae of HBV infection, independent of HBeAg status. While risk for cirrhosis and for HCC notably increases at HBV-DNA levels ≥10 000 copies/mL, low-level viremia was also associated with significant risk for HCC.

Keywords: Africa, cirrhosis, HBV, HCC, viral load.

INTRODUCTION
Hepatitis B virus (HBV) is the leading cause of hepatocellular carcinoma (HCC) worldwide, particularly in Asia and sub-Saharan Africa [1]. In these endemic regions, HBV infection is generally acquired at birth or in early childhood with up to 10–20% of the adult population persistently expressing HBV surface antigen (HBsAg, a serologic marker of chronic infection) [2]. Persons with HBsAg expression are at very high risk of developing the chronic sequelae of HBV infection including liver cirrhosis and HCC. However, despite the very high attributable fraction and relative risk related to HBsAg positivity, only a minority of chronically infected persons will develop cirrhosis or HCC. The role of environmental or behavioural factors (e.g., aflatoxin exposure, alcohol use) and of host genetic factors have been documented to modify individual risk for HCC [3–5]. In addition, growing evidence indicates that differences in HBV outcomes may be closely associated with viral characteristics, including replication status and genetic variation of HBV [3,6,7]. Recent studies conducted in large Asian cohorts indicate that HBV-DNA levels strongly predicted development of HBV-related cirrhosis and HCC [8–10]. In contrast to Asia, there are only limited data on HBV-DNA detection and quantification associated with liver disease outcomes among persons from sub-Saharan Africa.

Hepatitis B virus infection is endemic in The Gambia in West Africa with a 15–20% prevalence among adults [11,12]. HCC is the most common cause of cancer and one of the leading causes of death among Gambians [13]; HBV...
accounts for around two-thirds of HCC cases [11]. Using
hybridization assays, we previously reported that high-titre
serum HBV DNA in adult HBV chronic carriers was corre-
lated with duration of HBV carriage and HBeAg positivity
[14]. However, HBV hybridization assays have limited sen-
sitivity and in response, we recently validated a sensitive
quantitative real-time polymerase chain reaction assay for
measuring serum HBV DNA among Gambian HBV carriers
[15]. In the current study, we apply this assay to measure
HBV-DNA levels in a well-characterized Gambian study
population that includes asymptomatic HBV carriers and
persons with HBV-related cirrhosis or HCC. We hypothesized
that a dose–response association of HBV-DNA level with
advanced liver disease would be observed. Thus, our primary
objectives were to define the occurrence and levels of HBV
viremia and examine their associations with cirrhosis and
HCC in an African population.

MATERIALS AND METHODS

Study participants

Our study population included all HBsAg-positive persons
that had been prospectively recruited into the Gambia Liver
Cancer Study (GLCS), as described previously [11]. Briefly,
participants were recruited from September 1997 through
January 2001 through liver disease referral clinics at three
tertiary hospital sites (Royal Victoria Hospital, Banjul;
Medical Research Council Hospital, Fajara; and Bansang
Hospital, Bansang). Incident cases of cirrhosis or of HCC
were identified from among patients with suspected liver
disease referred by local physicians or identified through
active surveillance of the wards and clinics by GLCS field
staff. All participants were administered a standardized
questionnaire and underwent a clinical examination and
venipuncture; persons with liver disease had a standardized
ultrasound examination performed. HCC was diagnosed
either by pathology or by a combination of ultrasonographic
evidence of space-occupying lesions and a serum α-fetoprotein
(AFP) level of ≥100 ng/mL. Among individuals without
pathologic or ultrasonographic evidence of HCC, cirrhosis
was diagnosed using an ultrasound scoring system previ-
ously validated to liver histology among HBV-infected per-
sons [10,16,17]. The quantitative cirrhosis score is derived
from the ultrasonographic evaluation of the liver surface,
liver parenchyma, caliber of intrahepatic blood vessels and
spleen size; scores of ≥7 were used to define cirrhosis [18].
Asymptomatic HBV carriers were identified from among
control participants without clinical evidence of liver disease
recruited from the outpatient general medical clinics of the
same hospital sites. Antiviral treatment active against HBV
was not available to study participants. Local and interna-
tional scientific and ethical review committees approved the
study protocol, and informed consent was obtained from
each participant.

Laboratory testing

Following processing within 24 h, blood specimens were
stored at either −20 or −70 °C depending on the planned
testing. AFP was detected and quantified by standard
radiometric assay methods (DiaSorin SA, Sallugia, Italy).
Aspartate aminotransferase (AST), alanine aminotransferase
(ALT) and total bilirubin levels were determined on clinical
samples using Roche COBAS MIRA Chemistry Analyzer.
HBsAg was determined by reverse passive haemagglutina-
tion assay (Murex Diagnostics Limited, Darlington, UK) with
radioimmunoassay testing of negative samples (Sorin
Biomedica Diagnostics, Vercelli, Italy). Participants positive
for HBsAg were tested for HBV e antigenemia (HBeAg) as a
surrogate marker of active replication using a radioimmuno-
assay kit (DiaSorin). HBV-DNA detection and quantifica-
tion were performed as described previously [15]. Briefly,
quantitative real-time PCR was carried out using commer-
cial SYBR-Green reaction mix (Qiagen, Hilden, Germany)
and primers specific to the S gene. The primer sequences
were 5′ GTG TCT GCG GCG TTT TAT CA (sense) and 5′ GAC
AAA CGG GCA ACA TAC CTT (antisense) designed to
amplify a 98 base pair product from positions 379 to 476 of
the HBV genome. Thermal cycling was performed in an ABI
5700 sequence detection system (PE Applied Biosystems,
Warrington, UK). HBV-DNA concentration was calculated
from a four point standard curve [1.5 × 10⁶, 1.5 × 10⁷,
1.5 × 10⁸ and 1.5 × 10⁹ copies/mL]. Calibration of this
standard was confirmed by comparison with an interna-
tional HBV-DNA standard (97/746; NIBSC, Potters Bar, UK).
The detection limit of the RT-PCR assay was 2.6 × 10¹ DNA
copies per mL [15], although the qualitative limit of detect-
ion for the assay was established as 2.0 × 10² DNA copies
per mL. Samples testing above the standard curve were
re-assayed at a dilution of 1:100. The assay was 100% specific
when tested against 10 HBV negative sera and intra-
and inter-assay comparisons demonstrated acceptable
reproducibility [15].

Statistical analysis

We calculated descriptive statistics for demographic and
clinical variables by study group. Geometric mean (GM) and
median HBV-DNA levels were determined based on observed
value for participants with quantifiable HBV DNA (≥260
copies/mL) and an estimate of 200 copies/mL for partici-
pants with non-quantifiable but qualitatively detectable HBV
DNA (200–259 copies/mL). We used chi-square, Fisher’s
exact, unpaired t and unbalanced analysis of variance tests
to evaluate differences among and between the three study
groups. We used unadjusted and adjusted logistic regression
models to evaluate the impact of HBeAg positivity, HBV-
DNA detection status and HBV-DNA level on risk of cirrhosis
or of HCC compared with control individuals. Based on prior
analysis [11], we included age, gender, recruitment site and

© 2009 Blackwell Publishing Ltd
date, education and household floor type in adjusted models. Education and household floor type were included in each analysis as markers of socioeconomic status. Participants’ tobacco, alcohol consumption and the presence of antibodies against hepatitis C virus did not qualitatively change any effect estimates, and were thus excluded from the final models. Three individuals with incomplete ascertainment of educational status were excluded from the analyses of risk for cirrhosis and HCC. All analyses were conducted using SAS 9.1 (SAS Institute, Cary, NC, USA).

RESULTS

Characteristics of study participants

Demographic and laboratory marker characteristics of the 60 asymptomatic HBV carriers, 53 HBV-related cirrhotic patients and 129 HBV-related HCC cases are presented in Table 1. All three groups were majority male with gender ratios ranging from 3.3 to 5.3 males per female. The majority of participants were under 45 years of age with minimal differences in this proportion by study group (asymptomatic carriers, 61%; cirrhosis cases, 63%; HCC cases, 59%). Study participants often lived in homes with earthen floors but most had received at least some formal schooling. Recruitment site and socioeconomic status variables did not differ significantly between the three study groups. Cigarette smoking was relatively common in this population although alcohol consumption was not (data not shown); the proportions of smokers and drinkers did not vary significantly between the study groups. Elevated AST and bilirubin levels were seen more frequently in the cirrhosis and HCC case groups compared to asymptomatic carrier group (both \( P < 0.01 \), while the occurrence of elevated ALT was infrequent and similar across the three groups.

HBV markers by study group and demographic variables

Circulating HBeAg was detected in only 3% of asymptomatic carriers compared to 28% and 18% of cirrhosis and HCC cases respectively (Table 2). When examining the distribution of HBeAg positivity by age group (Fig. 1a), the proportion of cirrhosis and HCC cases who were HBeAg positive was higher than among asymptomatic carriers regardless of age; notably, we did not detect HBeAg among any asymptomatic HBV carriers over 44 years of age. Cirrhosis cases tended to have a higher proportion with HBeAg expression than HCC cases across most age strata.

Cirrhosis and HCC cases more commonly had detectable HBV viremia and higher viral load levels compared to asymptomatic HBV carriers (Table 2). Over 80% of cirrhosis

and HCC cases had HBV-DNA detected compared to only 42% of asymptomatic carriers (P < 0.01 for both comparisons). Among those participants with detectable HBV DNA, the GM of HBV-DNA levels among cirrhosis cases (6.46 log10 copies/mL) and HCC cases (5.80 log10 copies/mL) were more than 2 to 3 log10 higher, respectively, than observed among asymptomatic carriers (3.62 log10 copies/mL; P < 0.01 for both comparisons). Similar relationships by study group were also observed when median HBV-DNA levels were examined with 1247 copies/mL, 6398892 copies/mL and 323443 copies/mL for controls, cirrhosis and HCC cases, respectively. The findings of a lower proportion of viremia and lower viral load among asymptomatic carriers compared to subjects with advanced liver disease was consistently observed across all age groups (Fig. 1b, c).

Hepatocellular carcinoma cases 55 years of age and older tended to have a lower proportion of HBV-DNA detection (75%) compared to younger HCC cases (90.8% HBV DNA

© 2009 Blackwell Publishing Ltd
positive among those <55 years, \( P = 0.058 \)). In contrast, all cirrhosis cases 55 years of age and older had detectable HBV DNA compared to 79.2% among younger cirrhosis cases \( P = 0.57 \). Overall, HBV-DNA levels among cirrhosis cases were higher (~0.75 log10) than that of HCC cases \( P = 0.05 \). Further, this relationship of higher HBV-DNA levels among cirrhosis cases compared to HCC cases was observed within all age strata except for the youngest grouping of persons under 35 years of age (Fig. 1bc).

The distribution of HBV-DNA detection and viral loads within study groups, stratified by HBeAg status, are presented by age groupings and by gender in Table S1. HBeAg was perfectly predictive of HBV viremia as all HBeAg positive participants were also HBV-DNA positive. However, despite the commonly referenced use of HBeAg as a marker of HBV viral replication, 40% (23/58) of asymptomatic carriers, 74% (28/38) of cirrhosis cases and 86% (91/106) of HCC cases that were HBeAg negative had detectable HBV DNA \( P = 0.01 \). GM viral loads were significantly higher among HBeAg positive compared with HBeAg negative cirrhosis and HCC cases \( P < 0.01 \) for both. The two HBeAg positive asymptomatic carriers displayed much higher HBV-DNA levels compared with 58 HBeAg negative carriers; however, this comparison was limited by small numbers and was of borderline statistical significance \( P = 0.05 \). Among HBeAg negative participants, higher HBV-DNA levels among cirrhosis cases compared with HCC cases were observed across all ages represented in the study.

Overall, male and female participants had similar proportions with detectable HBV DNA (76% vs 70%, respectively; \( P = 0.42 \)) and GM viral loads (478 319 vs 356 034, respectively; \( P = 0.77 \)). Gender-specific data on HBV-DNA detection and viremia stratified by study group and HBeAg status are presented in Table S1. Among HBeAg negative participants, males displayed higher HBV-DNA levels compared with females within each study group. In contrast, among HBeAg positive participants, males had lower HBV viral loads than females within each study group. However, these gender comparisons of HBV-DNA levels were limited by many strata having relatively small numbers, particularly for HBeAg positive women.

persons provides valuable information for estimating risk for both cirrhosis and HCC. Our findings extend the utility of HBV-DNA measurements for predicting cirrhosis or HCC risk to include HBV-infected persons from sub-Saharan Africa. Further, despite the well-recognized difference in circulating HBV genotypes and the prevalence of viral mutations between Asian and African populations, we provide additional support that the threshold of 10 000 copies/mL of HBV DNA is important in the decision of antiviral treatment candidacy. However, our data raise further questions regarding the HCC risk associated with detectable HBV DNA at levels <10 000 copies/mL, and as such, appropriate management of persons with lower level HBV replication.

The recognition that relatively few chronic HBsAg-positive carriers manifest complications of HBV, the appreciation that productive viral replication commonly occurs in the absence of HBeAg, and the need for determining eligibility and for monitoring anti-HBV therapy all highlight the need for improved HBV biomarkers. Our current study applied a previously validated in-house RT-PCR assay to measure HBV-DNA levels among well-characterized participants in the Gambia Liver Cancer Study [11,15]. Importantly, all risk estimates associated with HBV-DNA measurements were in comparison with chronically infected, but asymptomatic persons expressing HBsAg of similar age to the cases. Our application of sensitive real-time PCR methods could detect low levels of HBV viremia. Simple categorization of HBV viremia as present was associated with a sixfold and a 12-fold increased risk for cirrhosis or HCC respectively. Further, we identified a dose–response increase in HCC risk with increasing levels of HBV DNA, up to a 39-fold risk associated with levels >10 000 copies/mL.

Large-scale cohorts with lengthy follow-up among Taiwanese HBV carriers have provided prospective data documenting an increased risk for cirrhosis and for HCC with increasing levels of HBV DNA [7,8,10]. Because of the differences in study design, risk estimates for cirrhosis and HCC with HBV viremia reported from our case–control study with HBV DNA measured at diagnosis, may not be directly comparable with estimates from the Asian cohort studies with HBV DNA measured on stored samples obtained 10–15 years prior to diagnosis [10]. If HBV-DNA levels decline over time to a greater degree among asymptomatic carriers compared with persons who develop advanced disease, risk estimates based on levels measured at diagnosis may overestimate risk. Conversely, if HBV DNA declines are accelerated among diseased compared to non-diseased, our risk estimates would be underestimated. Finally, if declines in HBV-DNA levels are comparable between persons who develop disease and similarly aged carrier controls, the risk estimates should also be comparable.

Only limited data are available to evaluate persistence of HBV-DNA levels. Chen and colleagues evaluated HBV-DNA levels from the visit just prior to HCC diagnosis on subjects with baseline HBV-DNA levels >10 000 copies/mL (median duration of interval follow-up was ~10 years) [9]. HCC risk was most closely predicted by the proximate HBV-DNA measure; baseline levels of 10 000–99 000 copies/mL were not associated with significantly increased risk except among the 21% of persons with HBV-DNA levels increasing to >100 000 copies/mL. In subsequent detailed analysis of long-term HBV viral load measures in this cohort, the authors reported that while HCC cases had higher baseline viral loads, their HBV-DNA levels decreased more rapidly during follow-up compared to non-cases [19]; this suggests that our case–control study risk estimates may in fact be conservative. Importantly, if the baseline HBV-DNA measure was greater than ~10 000 copies/mL in the Taiwanese cohort, the probability of maintaining stable levels above this threshold was high. Their data suggest that persistently elevated HBV-DNA levels are most predictive of developing HCC and support our premise that these markers are durable and useful for estimating risk later in the disease process.

Despite a similar overall prevalence of HBV carriage, there are marked differences in HBV infection between Asian and African populations. While perinatal transmission is common in Asian populations, horizontal transmission among young children predominates in Africa [2]. Differences in circulating HBV genotypes, HBeAg persistence, host genetics and exposure to cofactors such as aflatoxin may also contribute to a differing course of HBV infection between Asians and Africans. With all these population differences, it is remarkable that our findings from The Gambia are largely consistent with the prior Asian studies.
To our knowledge, only one prior study estimated HCC risk related to HBV-DNA measurements in an African population. Among 14 HCC cases matched to 22 HBsAg positive controls identified in a cohort of males in the Senegalese Army, Tang and colleagues reported a 16-fold increased risk with HBV-DNA detection [20], comparable to our risk estimate of 12.1 (Table 3).

Consistent findings suggest that risk for HCC associated with HBV-DNA levels increases in a dose–response fashion, but it remains unclear at what lower limit HCC risk may be negligible. Determination of the ‘safe’ threshold of HBV-DNA levels where the development of HBV-related complications is unlikely is of great importance in determining appropriate screening and antiviral management guidelines.

Prior studies of HBV viremia have largely focused on HCC as the primary endpoint. Chen and colleagues reported risk for cirrhosis and HCC outcomes achieving statistical significance at ≥10,000 copies/mL [9,10]. In a large prospective cohort in Haimen City in China, significantly increased risk for HCC and cirrhosis mortality was not observed until ≥100,000 copies/mL. Our data suggested that while lower level viremia (200–10,000 DNA copies/mL) was significantly associated with HCC, risk for cirrhosis did not increase until ≥10,000 copies/mL. Interestingly, we found that HBV-DNA levels appeared to be higher among cirrhotic compared to non-cirrhotic HCC. Although viral factors largely did not differ between HBV-related non-cirrhotic compared to cirrhotic HCC in a Taiwanese study, there was a borderline association of higher viral load in cirrhotic HCC [21]. Younger HCC patients with lower HBV viral loads are less likely to have coexistent cirrhosis compared to older HCC cases with higher viremia [22].

These epidemiologic data can suggest mechanisms that may be involved in the pathogenesis of HBV-related cirrhosis and HCC. Replicative HBV infection is the stimulus for host immune responses leading to the chronic process of hepatocyte destruction and regeneration with development of fibrosis and eventually cirrhosis. As such, it may be that a certain threshold level of HBV replication is required to lead to development of cirrhosis.

It remains unclear whether HBeAg plays a direct biological role or merely represents a long-recognized surrogate marker for HBV replication [23]. HBeAg positivity is strongly associated with increased risk for HCC [6,11] while HBeAg seroconversion is mostly accompanied by resolution of necroinflammatory liver changes and reduced or undetectable HBV-DNA levels [24,25]. In our study, while all HBeAg positive participants were HBV-DNA positive, less than half of HBeAg negative asymptomatic carriers had detectable viremia. However, only 15–25% of those with cirrhosis or HCC expressed HBeAg at diagnosis. The incremental value of HBeAg status to predict liver disease risk was assessed (Table 3); interestingly, risk estimates for both cirrhosis and for HCC related to HBeAg positivity were reduced by almost half after accounting for HBV viremia. Assessment of the role of HBeAg-negative variants in relation to HBV-DNA levels and disease outcomes will be key to fully understand the mechanisms involved.

Our study had several challenges. Despite being one of the largest of the few studies of HBV DNA in HCC or cirrhosis from Africa, some of our analyses were limited by having small numbers. As discussed above, the cross-sectional nature of our study evaluates HBV-DNA levels at time of diagnosis so the disease process itself may impact our measured levels. While we are unable to equivocally state what long-term predictive value HBV-DNA levels have in estimating risk for HBV-related liver disease, the consistency of our findings to previous studies, especially those with testing near time of diagnosis, supports our ability to make strong inferences.

In conclusion, we find that HBV-DNA levels are strongly associated with the serious sequelae of HBV infection, independent of HBeAg status. While risk for cirrhosis and for HCC notably increases at HBV-DNA levels ≥10,000 copies/mL, low-level viremia was also associated with significant risk for HCC. Growing evidence suggests that suppression of HBV, even if only for a finite time period, may significantly reduce risk for developing HCC [26]. Further application of sensitive HBV-DNA assays to appropriate study populations should improve our ability to target HBV-infected persons at highest risk for disease progression and most appropriate for antiviral therapy. In recent years, the successful introduction and dissemination of antiviral therapy for HIV infection (commonly including drugs with anti-HBV efficacy) in sub-Saharan Africa raises expectations that resource-constrained HBV-endemic regions of the world may also improve access to appropriate HBV treatment. Clearly, randomized trials of HBV therapies in these affected regions, with longer term follow-up to determine reductions in development of cirrhosis or HCC, are needed.

ACKNOWLEDGEMENTS AND DISCLOSURES

We would like to thank the staff of the Gambia Liver Cancer Study and The Gambia Hepatitis Intervention Study and the staff and participants at the Bunsang, Medical Research Council and Royal Victoria hospitals for their contributions. We thank Adam-Jeng Barry for excellent technical assistance. We gratefully acknowledge the financial support of the National Cancer Institute (Contract N02-CP40521) and Medical Research Council (Fajara, The Gambia and United Kingdom).
