Evidence regarding the effectiveness of laser photocoagulation of drusen to prevent progression to age-related macular degeneration has been updated. A Cochrane systematic review comparing laser photocoagulation to no intervention found that it may reduce the risk of choroidal neovascularisation (CNV) and geographic atrophy (GA) but the evidence is not conclusive. More studies are needed to confirm these findings and determine the optimal treatment strategy.

**Background**

Drusen are amorphous yellowish deposits beneath the sensory retina. People with drusen, particularly large drusen, are at higher risk of developing age-related macular degeneration (AMD). The most common complication in AMD is choroidal neovascularisation (CNV), the growth of new blood vessels in the centre of the macula. The risk of CNV is higher among people who are already affected by CNV in one eye.

It has been observed clinically that laser photocoagulation of drusen leads to their disappearance and may prevent the occurrence of advanced disease (CNV or geographic atrophy) associated with visual loss.

**Objectives**

To examine the effectiveness and adverse effects of laser photocoagulation of drusen in AMD.

**Search methods**

We searched CENTRAL (which contains the Cochrane Eyes and Vision Group Trials Register) (2015, Issue 7), Ovid MEDLINE, Ovid MEDLINE In-Process and Other Non-Indexed Citations, Ovid MEDLINE Daily, Ovid OLDMEDLINE (January 1946 to August 2015), EMBASE (January 1980 to August 2015), Latin American and Caribbean Health Sciences Literature Database (LILACS) (January 1982 to August 2015), the ISRCTN registry (www.isrctn.com/editAdvancedSearch), ClinicalTrials.gov (www.clinicaltrials.gov) and the World Health Organization (WHO) International Clinical Trials Registry Platform (ICTRP) (www.who.int/ictrp/search/en). We did not use any date or language restrictions in the electronic searches for trials. We last searched the electronic databases on 3 August 2015.

**Selection criteria**

Randomised controlled trials (RCTs) of laser treatment of drusen in AMD in which laser treatment had been compared with no intervention or sham treatment. Two types of trials were included. Some trials studied one eye of each participant (unilateral studies); other studies recruited participants with bilateral drusen and randomised one eye to photocoagulation or control and the fellow eye to the other group.
Data collection and analysis

Two review authors independently selected studies and extracted data. We pooled data from unilateral and bilateral studies using a random-effects model. For the bilateral studies, we estimated the within-person correlation coefficient from one study and assumed it was valid for the others.

Main results

The update of this review found two additional studies, totaling 11 studies that randomised 2159 participants (3580 eyes) and followed them up to two years, of which six studies (1454 participants) included people with one eye randomised to treatment and one to control. Studies were conducted in Australia, Europe and North America.

Overall, the risk of bias in the included studies was low, particularly for the larger studies and for the primary outcome development of CNV. Photocoagulation did not reduce the development of CNV at two years’ follow-up (odds ratio (OR) 1.07, 95% confidence interval (CI) 0.79 to 1.46, 11 studies, 2159 participants (3580 eyes), high quality evidence). This estimate means that, given an overall occurrence of CNV of 8.3% in the control group, we estimated an absolute risk reduction by no more than 1.4% in the laser group, according to the lower CI limit. Only two studies investigated the effect on the development of geographic atrophy and could not show a difference, but estimates were imprecise (OR 1.30, 95% CI 0.38 to 4.51, two studies, 148 participants (148 eyes), low quality evidence).

Among secondary outcomes, photocoagulation led to drusen reduction (OR 9.16, 95% CI 6.28 to 13.4, three studies, 570 participants (944 eyes), high quality evidence) but was not shown to limit loss of 3 or more lines of visual acuity (OR 0.99, 95% CI 0.81 to 1.22, nine studies, 2002 participants (2386 eyes), moderate quality evidence).

In a subgroup analysis, no difference could be shown for conventional visible (eight studies) versus subthreshold invisible (four studies) photocoagulation for the primary outcomes (P value = 0.29). The effect in the subthreshold group did not suggest a relevant benefit (OR 1.27, 95% CI 0.82 to 1.98). No study used micropulse subthreshold photocoagulation.

No other adverse effects (apart from development of CNV, geographic atrophy or visual loss) were reported.

Authors’ conclusions

The trials included in this review confirm the clinical observation that laser photocoagulation of drusen leads to their disappearance. However, treatment does not result in a reduction in the risk of developing CNV, and was not shown to limit the occurrence of geographic atrophy or visual acuity loss.

Ongoing studies are being conducted to assess whether the use of extremely short laser pulses (i.e. nanosecond laser treatment) cannot only lead to drusen regression but also prevent neovascular AMD.

Plain Language Summary

Laser treatment of drusen to prevent progression to advanced age-related macular degeneration

Review question

We reviewed the evidence about the effect of laser treatment of the centre of the retina in people with macular drusen to prevent the occurrence of the more advanced type of age-related macular degeneration (AMD).

Background

Drusen are yellowish deposits that can be seen in the macula (the centre of the retina) in a larger proportion of people as they get older. People with drusen, particularly extensive large drusen, are at higher risk of developing AMD. The most common complications in AMD are the growth of new blood vessels in the centre of the macula (called choroidal neovascularisation (CNV), also known as ‘wet AMD’) and loss of retinal cells or photoreceptors in the macula (called geographic atrophy). It has been observed clinically that making very small burns around the macula with laser light (laser photocoagulation) makes drusen disappear. Laser photocoagulation of drusen has thus been proposed as a way to prevent the development of CNV and geographic atrophy. More recently, subthreshold photocoagulation has been used to cause invisible laser burns and achieve drusen reduction with less damage to the retinal structure.
The evidence is current to 3 August 2015.

**Study characteristics**

This review included data from 11 trials conducted in Australia, Europe and North America. The studies followed up 2159 participants with drusen (3580 eyes) to two years, of which six studies (1454 participants) included people with one eye randomised to treatment and one to control. Four studies (850 eyes) used subthreshold photocoagulation.

**Study funding sources**

Three out of four studies using laser subthreshold photocoagulation were sponsored by the laser producer.

**Key results**

These studies showed that laser photocoagulation of drusen leads to their disappearance. However, laser photocoagulation of drusen did not reduce the risk of developing CNV, which was about 10% at three years in untreated participants. A smaller number of studies reported on the development of geographic atrophy, that is, atrophy in the centre of the macula, but these studies were inconclusive and the effect of laser treatment of drusen on the development of geographic atrophy was uncertain. The risk of visual loss was similar in treated and untreated groups. There was no suggestion that a benefit may exist with subthreshold photocoagulation.

**Quality of the evidence**

The overall quality of the evidence was high regarding failure to prevent CNV, but it was low for prevention of atrophy due to the small number of participants for whom this outcome was assessed.

* The basis for the **assumed risk** (e.g., the median control group risk across studies) is provided in footnotes. The **corresponding risk** (and its 95% confidence interval) is based on the assumed risk in the comparison group and the **relative effect** of the intervention (and its 95% CI).

CI: confidence interval; CNV: choroidal neovascularisation; OR: odds ratio

**GRADE Working Group grades of evidence**

- **High quality:** Further research is very unlikely to change our confidence in the estimate of effect.
- **Moderate quality:** Further research is likely to have an important impact on our confidence in the estimate of effect and may change the estimate.
- **Low quality:** Further research is very likely to have an important impact on our confidence in the estimate of effect and is likely to change the estimate.
- **Very low quality:** We are very uncertain about the estimate.

---

1. Allocation sequence generation and allocation concealment and masking of visual acuity outcome assessors was achieved in half or less of them; however, the larger studies in this meta-analysis were good quality. Other quality items were not a problem for the primary outcome (no downgrade).
2. Small study yielding wide 95% confidence intervals (-2 for imprecision).
3. Visual acuity examiners were masked in less than half of studies (-1 for risk of bias).
4. The three studies included in this analysis had low risk of bias (no downgrade).
5. Estimates were heterogeneous but they both suggest a strong effect (no downgrade).
BACKGROUND

Description of the condition

Age-related macular degeneration (AMD) is the leading cause of vision loss in industrialised countries (Klein 2004; Vingerling 1996). Early AMD is characterised by focal or diffuse depositing of extracellular material between the retinal pigment epithelium (RPE) and Bruch's membrane, forming drusen (focal deposits) or basal laminar deposits (diffuse deposits) (Bressler 1994; Sarks 1999; Young 1987). This process is associated with progressive degeneration of PRE and photoreceptor cells (Guidry 2002; Phipps 2003; Young 1987). Advanced AMD is characterised by the development of geographic atrophy (characterising the non-exudative AMD form) or choroidal neovascularisation (CNV; characterising the exudative AMD). When the fovea, which represents the centre of vision, is involved by atrophic or exudative manifestations of AMD, a severe visual loss results.

Advanced AMD has a prevalence that increases markedly with age (EDPRG 2004; Owen 2003). In the US, advanced AMD prevalence is 3.5% in white men and 4% in white women at 75 to 79 years (EDPRG 2004). Based on one systematic review of UK studies, Owen 2003 reported that there were approximately 214,000 people with visual impairment caused by AMD. In this study, the ratio of neovascular AMD to geographic atrophy was about 2 : 1, such as in Smith 2001. Ten years later, Owen 2012 estimated 513,000 prevalent cases of late AMD, of which 263,000 were neovascular AMD. Rudnicka 2015 conducted a systematic review and estimated 293,000 incident cases of late AMD each year in the U.S.A.

Drusen results from deposition of the photoreceptors' debris, which are composed of lipofuscin and membranous deposits. Drusen appear when sufficient material has been deposited, clinically characterised by amorphous yellowish deposits beneath the sensory retina. Four main types of drusen can be detected in the retina. Hard drusen are discrete, yellow, nodular deposits, smaller than 50 μm in diameter. Basal laminar drusen are tiny, whitish, multiple deposits with a 'starry night' appearance. Soft drusen are yellowish deposits with poorly defined margins, tending to coalesce, and are usually larger than 50 μm. Crystalline drusen are discrete, calcific, refractile deposits. Drusen characteristics associated with a high risk of progression to exudative AMD (high-risk drusen) include: soft drusen, more than five, larger size (greater than 63 μm), drusen confluence and associated hyperpigmentation.

The cumulative incidence of new exudative or atrophic lesions in eyes initially free of advanced AMD has been estimated as 8.6% at one year, 16.4% at two years and 23.5% at three years (Holz 1994). Focusing on the CNV incidence, the results of a prospective investigation of people with exudative manifestation in one eye and drusen in the fellow eye has shown that the risk of developing CNV peaks at four years, dissipating thereafter, whereas there is a slightly increased incidence of geographic atrophy in the longer term (Sarraf 1999). Moreover, the five-year risk of CNV occurrence in the fellow eye of people who have already experienced CNV in the first eye, varies from 7% to 87% depending on the co-existence of four main risk factors (presence of five or more drusen, focal hyperpigmentation, one or more large drusen and systemic hypertension) (MPSG 1997).

Drusen can spontaneously disappear in people with AMD, generally leaving atrophic lesions. More specifically, the Waterman study has reported that disappearance of large drusen occurred in 16/47 (34%) participants in one five-year longitudinal study (Bressler 1995).

Description of the intervention

Laser treatment is based on the release of a powerful beam of light that, combined with ophthalmic equipment and lenses, can be precisely focused on the retina to treat some diseases. The laser energy causes a certain amount of controlled damage to the tissues in order to obtain the desired effect. Small laser burns are usually employed to obliterate or destroy abnormal blood vessels or other lesions in the eye.

Several observers noted that laser application can lead to drusen being resorbed in the macular area (Cleasby 1979; Gass 1973; Gross-Jendroska 1998; Wetzig 1994). Owing to the risk of vision loss associated with the presence of high-risk drusen, laser application was proposed as an intervention to prevent progression to advanced AMD. Laser burns are applied to the retina, either directly to the drusen or following pre-defined patterns. Argon, krypton, dye or diode lasers have been used with varying levels of energy (achieving from not visible to faint or intense whitish retinal lesions). The spot size used varies between 100 and 200 μm and number of spots from less than 10 to nearly 300.

Subthreshold laser therapy is a more recent application of laser energy to retinal diseases. The theoretical advantage of subthreshold laser is based on minimising the damage to the retinal tissue by ensuring the energy spreads as little as possible. This aim can be achieved by reducing the duration of laser exposure and operating with a sub-visible clinical endpoint. As a result, no laser scar is produced in the retina, obtaining at the same time equivalent clinical effects of conventional laser treatment (Sivaprasad 2010).

Several studies have shown that subthreshold laser photocoagulation can be a viable option for several disorders, including diabetic macular oedema (Lavinsky 2011; Luttrull 2012), macular oedema secondary to branch retinal vein occlusion (Parodi 2006; Parodi 2008), and macular drusen. Subthreshold photocoagulation encompasses a range of techniques, among which micropulse subthreshold photocoagulation delivers light energy with very short impulses that are absorbed by the RPE only, aiming to spare the neurosensory retina.
How the intervention might work

The mechanisms of laser-induced drusen regression are only speculative. Laser treatment may lead to an increased clearance of debris by choroidal phagocytic cells or macrophages. Alternatively, laser application may improve egress of drusen material through a thinner or more permeable Bruch's membrane, with the consequent reduction of its outflow resistance. Laser effect may manifest by triggering retinal pigment epithelial proliferation leading to the production and release of cytokines and growth factors. These molecules may be able to modify the biochemical process underlying the clinical manifestations of the retinal disorder, rather than simply destroying drusen, and may also act on the drusen remote from the site of the laser energy application (Abdelsalam 1999; Frennesson 1998; Pauleikhoff 1990a; Pauleikhoff 1990b). Histopathological examinations in animal models have shown that phagocytic cells, probably derived from choriocapillaris pericytes, can remove drusenoid material after laser photocoagulation (Duvall 1985). Protrusion of choroidal endothelial cell processes into Bruch's membrane are enhanced by laser photocoagulation and may play a part in the clearance of debris from the Bruch's membrane (Guymer 2001).

Micropulse laser delivery tries to achieve photostimulation rather than photocoagulation (Luttrull 2012). However, the mechanism of photocoagulation itself is poorly known, as reported above, thus we also include micropulse photocoagulation in this review. Picosecond laser treatment has been attempted to achieve drusen reduction and prevent CNV, a treatment that was defined “retinal rejuvenation therapy (2RT)” (Guymer 2014). Using very short laser pulses (3 ns), an insult caused by steam production around melanosomes can be confined to the RPE inducing a highly selective and discrete non-thermal injury. It has been hypothesised that a 3-ns laser could induce migration of RPE cells and release of matrix metalloproteinases, improving the hydraulic conductivity of Bruch's membrane. The hope is to achieve a prophylactic treatment of early AMD without the potential harmful effects seen with traditional thermal lasers.

Why it is important to do this review

AMD is a major public health problem in developed economies where the life expectancy is greatest (but of no significance in poorer countries with a life expectancy of under 65 years of age). Several investigations about health-related and vision-targeted features have shown that AMD is associated with decreased quality of life (Brown 2006; Chakravarthy 2005; Hassell 2006; Maguire 2004; Mangione 1999). Although people with drusen experience few visual symptoms, once advanced AMD is present, visual loss is generally irreversible. It has been shown that people with drusen who take antioxidant supplementation are less likely to lose 15 or more letters of visual acuity over the follow-up (AREDS 2001), even though this benefit was considered modest in people with moderate to severe signs of the disease (Evans 2012). Antioxidants have not been shown beneficial in the primary prevention of AMD (Chong 2007). Thus, the identification of a prophylactic treatment able to reduce the complications related to AMD may be highly beneficial. Laser treatment of drusen appeared to provide positive results in observational studies (Cleasby 1979; Gass 1973; Gross-Jendroska 1998; Sigelman 1991; Wetzig 1994). A systematic review is necessary to ensure that all the evidence on this intervention is considered objectively. People with AMD and their carers need to have recommendations as to the possible benefits or harms of this intervention.

OBJECTIVES

To examine the effectiveness and adverse effects of laser photocoagulation of drusen in AMD.

METHODS

Criteria for considering studies for this review

Types of studies

We included only randomised controlled trials (RCTs) of laser treatment of drusen in AMD.

Types of participants

People with retinal drusen associated with AMD in one or both eyes.

Types of interventions

We included trials in which laser treatment for retinal drusen was compared with no intervention or sham treatment. We considered a variety of different laser sources and photocoagulation techniques.

Types of outcome measures

Primary outcomes

- Progression of AMD as measured by the development of CNV.
- Progression of AMD as measured by the development of geographic atrophy.
Secondary outcomes
- Loss of visual acuity (LogMAR (logarithm of the Minimum Angle of Resolution) values);
- Changes in contrast sensitivity;
- Drusen reduction;
- Changes in reading ability;
- Vision-related quality of life.

Visual acuity is generally measured using a standard chart, the ETDRS (Early Treatment of Diabetic Retinopathy Study) chart and scored in letters. There are five letters per line in this chart. We extracted both dichotomous outcomes, such as moderate (3 lines or 15 ETDRS letters) and severe (6 lines or 30 ETDRS letters) visual loss and continuous measures (mean visual acuity) when possible. Whenever no ETDRS values were used, we converted visual acuity to LogMAR for pooling data.

Contrast sensitivity is generally measured with the Pelli-Robson chart. Scores are collected in letters or as logarithm of contrast sensitivity. We used the logarithm of contrast sensitivity for pooling data when feasible. We extracted both continuous and dichotomous measures if possible. For dichotomous data, we recorded the proportion of participants with a change of at least 0.3 (corresponding to a two-fold change) or 0.6 log-units (corresponding to a four-fold change).

In the protocol, we planned to evaluate drusen reduction considering the number of eyes showing at least a 50% reduction of drusen area from the baseline aspect. However, data were sparsely reported and, therefore, we modified the protocol to allow an extraction based on the investigators’ definition.

We converted reading ability measures to LogMAR for reading acuity, whereas we considered reading speed as the logarithm of the number of words read in one minute.

Timing of outcome assessment
We assessed outcomes at 24 months, where data were available.

Adverse effects
We recorded adverse effects as documented in the included trials but noted that the main complication of laser was visual loss, especially due to CNV, which is considered under Primary outcomes and Secondary outcomes.

Microperimetry could be used to measure retinal sensitivity in laser-treated perimacular areas in future studies, especially if the aim is to document the presumed absence of damage expected with subthreshold micropulse or nanosecond laser treatment. Thus, we will extract such measure if available in future updates.

Search methods for identification of studies

Electronic searches
We searched CENTRAL (which contains the Cochrane Eyes and Vision Group Trials Register) (2015, Issue 7), Ovid MEDLINE, Ovid MEDLINE In-Process and Other Non-Indexed Citations, Ovid MEDLINE Daily, Ovid OLDMEDLINE (January 1946 to August 2015), EMBASE (January 1980 to August 2015), Latin American and Caribbean Health Sciences Literature Database (LILACS) (January 1982 to August 2015), the ISRCTN registry (www.isrctn.com/editAdvancedSearch), Clinical-Trials.gov (www.clinicaltrials.gov) and the World Health Organization (WHO) International Clinical Trials Registry Platform (ICTRP) (www.who.int/ictrp/search/en). We did not use any date or language restrictions in the electronic searches for trials. We last searched the electronic databases on 3 August 2015.

See: Appendices for details of search strategies for CENTRAL (Appendix 1), MEDLINE (Appendix 2), EMBASE (Appendix 3), LILACS (Appendix 4), ISRCTN (Appendix 5), ClinicalTrials.gov (Appendix 6), and the ICTRP (Appendix 7).

Searching other resources
We searched the reference lists of retrieved articles for details of further relevant studies. We did not handsearch journals or conference proceedings specifically for this review.

Data collection and analysis

Selection of studies
Two review authors independently assessed the titles and abstracts resulting from the electronic searches for inclusion. We obtained copies of all relevant or potentially relevant trials and assessed these according to the Criteria for considering studies for this review. The review authors were not masked as to the names of authors, institutions, journal of publication or results when making their assessments. We resolved disagreements about whether a trial should be included by discussion and consensus. In cases where additional information was needed before a decision was made whether to include a trial, we obtained this information by contacting the authors.

Data extraction and management
We recorded information about the methods used in the trial on a form including details of participants, details of intervention, outcomes and other information. Two review authors independently extracted the data for the primary outcomes, secondary outcomes and adverse effects onto paper forms. Since the double-entry facility is no longer available in Review Manager 5, one review author extracted data and entered them into Review Manager 5 for the update (RevMan 2014), and another review author checked the entries for errors and inconsistencies.
Assessment of risk of bias in included studies

Two review authors independently assessed the included trials for bias according to the methods described in Chapter 8 of the 
Cochrane Handbook for Systematic Reviews of Interventions (Higgins 
2011a). With the update of review management software, we as-
essed risk of bias using the tool set out in Higgins 2011a.
• Sequence generation: the method used to generate the 
allocation sequence, to assess whether it should have produced 
comparable groups.
• Allocation concealment: the method used to conceal the 
allocation sequence, to determine whether intervention 
allocations could have been foreseen in advance of, or during, 
enrolment.
• Masking of personnel and outcome assessors: the 
assessments were made for each main class of outcomes (i.e. 
anatomic versus functional outcomes) and we considered 
whether all measures used, if any, to mask study personnel from 
knowledge of which intervention a participant received were 
adequate.
• Incomplete outcome data: the assessments were made for 
each main class of outcomes (i.e. anatomic versus functional 
outcomes) when possible and were based on the description of 
the completeness of outcome data, including attrition and 
exclusions from the analysis and their causes, if they were 
reported.
• Selective outcome reporting: the possibility of selective 
outcome reporting, such as found when some measures were 
obtained, as declared in the methods section or in protocols, but 
not reported in the results section.

We used the following grading:
• low risk of bias: plausible bias unlikely to seriously alter the 
results;
• unclear risk of bias: plausible bias that raises some doubt 
about the results;
• high risk of bias: plausible bias that seriously weakens 
confidence in the results.

If the information available in the published trial reports was in-
adequate to assess any of the above items of the risk of bias as-
essment, we contacted the trial authors for clarification. If they 
did not respond within a reasonable period, we classified the trial 
based on the available information. When studies did not report 
any concealment approach, we considered adequacy unclear. We 
also assessed the impact of any assumptions made in this regard in 
a sensitivity analysis.

We considered a trial to have conducted an intention-to-treat anal-
ysis only if it included all participants who were randomised in-
cluding those randomised but not treated and excluded after ran-
domisation for other reasons.

Measures of treatment effect

We evaluated development of CNV and geographic atrophy on 
the basis of the percentage of their occurrence over the follow-up. 
We assessed visual acuity loss taking into consideration the loss of 
3 or more lines of visual acuity, which corresponds to a doubling 
of the visual angle if visual acuity is measured using a logMAR 
chart.

We planned to evaluate drusen reduction considering the number 
of eyes showing at least a 50% reduction of drusen area from 
the baseline aspect. However, data were sparsely reported and, 
therefore, we modified the protocol to allow an extraction based 
on the investigators’ definition.

Dichotomous data

Dichotomous data included, for example, progression of CNV or 
geographic atrophy, or loss of 3 or more lines of visual acuity. In 
the protocol, we stated that we would have used the risk ratio (RR) as 
our preferred measure of effect since we anticipated that the event 
rate would be greater than 10%. We actually found that the event 
rate was lower than this threshold in bilateral studies. Furthermore, 
to be able to manage data from unilateral and bilateral studies, 
we had to manipulate them using formulas proposed by Elbourne 
2002, which only apply to odds ratios (OR). Little difference is 
expected between RRs and ORs in this review, since the crude 
event rate was less than 10% in bilateral studies and less than 25% 
in unilateral studies, and also because the pooled OR was close to 
1.

Continuous data

Continuous data included, for example, reading speed. We used 
the mean difference (MD), unless the outcomes were measured 
on different scales in which case we used the standardised mean 
difference as the measure of effect.

Unit of analysis issues

Some trials identified a ‘study eye’ and randomised participants 
to treatment group. Other trials randomised the eye to treat-
ment and compared it with the other eye in the same person. We 
were careful to consider these trials separately at the data collection and 
extraction stage.

We did two sets of analyses for the primary outcome ‘development 
of CNV’. First, we pooled all the data ignoring the fact that the 
data from the bilateral studies were not independent. Second, we 
than did a sensitivity analysis assuming an intra-class correlation 
coefficient (ICC) of 0.5 for the development of CNV and 0.22 for 
visual acuity loss. We adjusted the standard errors using the meth-
ods given in Chapter 16 of the Cochrane Handbook for Systematic 
Reviews of Interventions (Higgins 2011b) and Elbourne 2002. See 
Appendix 7 for more details on the method used.

We used the generic inverse variance facility in Review Manager 
5 to enter the data for the sensitivity analysis (RevMan 2014).
Dealing with missing data

In the event that data were missing, we contacted the authors of the studies in an attempt to obtain more information. On the basis of the data we could collect, we first did an available case analysis. We recorded the amount of missing data in the included studies as shown in Table 1. At the time the protocol for this review was prepared, we planned that if missing data should prove to be a problem in the constituent studies, we would consider doing a sensitivity analysis considering outcome in the people lost to follow-up as either ‘all OK’ or ‘all not OK’ to see the range within which the true result might lie. This did not prove necessary at this stage. According to further guidance available in Chapter 8 of the Cochrane Handbook for Systematic Reviews of Interventions (Higgins 2011a), missing outcome data are not a problem if loss to follow-up is both balanced in the study arms of parallel arm studies and causes of loss are documented and judged to be unrelated to outcome in both study arms. When these conditions are not satisfied, a study can still be at low risk of bias if the outcome frequency is about 50% and loss to follow-up is below 10% in both arms (Higgins 2011a).

Because our primary outcomes were relatively rare in the complete case analysis in this review, and there were missing data of unreported cause, there was potential for bias due to incomplete outcome data in this review. In the updated version of this review, we considered missing data as at no risk of bias in bilateral studies because a participant with paired treatment and control eyes is missed. For each unilateral study, we assessed the risk of bias using methods described in Appendix 8, based on the users’ written function ‘metamiss’ in Stata 13.1 (StataCorp 2013) to conduct sensitivity analyses on primary outcome meta-analysis results by making different assumptions on informative missingness odds ratios (IMORs) across studies according to White 2008.

Finally, in the updated version of this review, we used the user written command extfunnel in Stata to assess the impact of a new study on the meta-analysis according to Langan 2012.

Assessment of heterogeneity

Before carrying out a meta-analysis, we assessed heterogeneity by examining the characteristics of the study, the forest plot of the results of the studies and the I² statistic to assess the presence of statistical heterogeneity.

Assessment of reporting biases

We investigated small-study bias using contour enhanced funnel plot (Peters 2008), and assessed significance of funnel asymmetry using Harbord’s test (Harbord 2006).

Data synthesis

We planned to perform a meta-analysis if there were sufficient trials available without substantial heterogeneity. We used a random-effects model unless there were three or fewer trials in which case we used a fixed-effect model. We compared fixed-effect and random-effects models to see how robust the results were.

Subgroup analysis and investigation of heterogeneity

We conducted the following subgroup analyses for the primary outcome ‘development of CNV’:

- type of laser treatment, mainly laser wavelength;
- clinically visible burns versus sub-threshold laser treatment.

Studies were duplicated when there were three arms and two different laser wavelengths were compared, and study arms were collapsed when unilateral and bilateral studies were published simultaneously.

Sensitivity analysis

We considered the results of between-person and within-person trials separately. We had planned to consider the effect of excluding poor quality studies, if there were sufficient studies. This was not done.

The methods for this review were published in the protocol (Parodi 2007).

Summary of findings

We prepared Summary of findings for the main comparison as per guidance given in Chapter 11 of the Cochrane Handbook for Systematic Reviews of Interventions (Schünemann 2011), and graded the overall quality of the evidence for each outcome using GRADE (GRADEpro 2015).

RESULTS

Description of studies

Results of the search

The original searches identified 111 reports of studies. We excluded Sarks 1999 and Sigelman 1991 because the treatment groups were not randomly allocated. Overall, nine trials were considered suitable for inclusion in the review of which two included both a unilateral and a bilateral arm with data available for both (DLS; Olk 1999), and four were only bilateral (CAPT; Figueroa 1994; Little 1995; PTAMD bilateral 2009). One study was published in abstract form only and the investigators supplied unpublished data for inclusion in this review (Laser to Drusen Study 1995).
An update search run in August 2015 identified a further 174 references (Figure 1). The Trials Search Co-ordinator removed 60 duplicates and screened the remaining 114 references, of which 59 were not relevant to the scope of the review. We reviewed the remaining 55 references and discarded 49 reports as not relevant. We obtained six full-text reports for potential inclusion in the review and included two new studies in the review (Frennesson 2009; PTAMD bilateral 2009). We excluded studies by Huang 2011 and Guymer 2014, see Characteristics of excluded studies table for reasons. We also added two ongoing studies, Beaumont 2011 and NCT01790802. Beaumont 2011 was only published as an abstract and the authors confirmed results still had to be published. NCT01790802 aimed to treat 250 participants with nanosecond laser treatment, starting in November 2011 with estimated study completion in June 2017.
Figure 1.  Study flow diagram.

9 studies included in previous version of the review (searches as of November 2008)

174 records identified through electronic database searching (November 2008 to August 2015)

114 records after duplicates removed

114 records screened by the Trials Search Co-ordinator (TSC)

58 records excluded by the TSC after initial screening

65 records screened by the authors

48 records excluded by the authors as not relevant

6 full-text reports assessed for eligibility

2 reports of 2 studies excluded with reasons

2 reports of 2 new studies included in the review

2 reports of 2 ongoing studies identified and data will be incorporated into the review when results become available

11 studies included in qualitative synthesis

11 studies included in quantitative synthesis
Included studies
See Characteristics of included studies table.

Types of studies
The study design was different across studies. Four studies included one eye of each participant (Frennesson 1995; Frennesson 2009; Laser to Drusen Study 1995; PTAMD unilateral 2002), and we refer to them as ‘unilateral’ studies. Four studies adopted a paired design whereby both eyes of the participant were included in the study, one eye randomly allocated to photocoagulation or control and the fellow eye to the other group (CAPT: Figueroa 1994; Little 1995; PTAMD bilateral 2009), and we refer to them as ‘bilateral’ studies. Three more studies included both a unilateral and a bilateral arm (CNVPT; DLS; Olk 1999). However, CNVPT did not report results from the bilateral study arm except for the number of participants with a gain of 1 or more lines of visual acuity at one year in an early report and, therefore, we could not extract data on this arm.

Types of participants
The 11 trials randomised 3629 people. The studies took place in the US (CAPT; CNVPT; Laser to Drusen Study 1995; Little 1995; Olk 1999; PTAMD bilateral 2009; PTAMD unilateral 2002), Sweden (Frennesson 1995; Frennesson 2009), Denmark (Frennesson 2009), Finland (Frennesson 2009), the UK (DLS), Germany (DLS), Australia (DLS), and Spain (Figueroa 1994). The mean age of the participants was approximately 70 years. The majority of participants were women in all studies (range 54% to 70%).

All studies recruited participants presenting medium (greater than 63 µm) or large (greater than 125 µm) drusen with pigmentary changes. CNVPT, DLS, Figueroa 1994, and Frennesson 2009 enrolled participants with bilateral macular drusen in the bilateral arm and participants with neovascular AMD in one eye and macular drusen in the fellow eye in a unilateral study. Little 1995, Olk 1999, Frennesson 1995, PTAMD bilateral 2009, and CAPT enrolled participants with macular drusen in both eyes.

Types of interventions
Table 2 gives details of the laser treatment employed in the different studies. Six studies employed argon laser, three diode laser and two dye laser. Laser spot size varied from 50 to 200 µm. The duration of each burn ranged from 0.05 seconds to 0.2 seconds. The number of laser spots included was between one and 100. PTAMD unilateral 2002 and PTAMD bilateral 2009 used subthreshold photocoagulation using an 810-nm diode laser in all treated participants. Frennesson 2009 used subthreshold photocoagulation using argon green laser. Olk 1999 used subthreshold photocoagulation in a random subset of treated eyes. Subthreshold photocoagulation was obtained by lowering the power that achieves standard photocoagulation and no study used micropulse photocoagulation.

Primary outcomes
Six bilateral studies or study arms (CAPT; DLS; Figueroa 1994; Little 1995; Olk 1999; PTAMD bilateral 2009), and seven unilateral studies or study arms (CNVPT; DLS; Frennesson 1995; Frennesson 2009; Laser to Drusen Study 1995; Olk 1999; PTAMD unilateral 2002) presented data on the outcome ‘development of CNV’.

We stated in the protocol that we aimed to obtain data at two years. However, we used three-year data for three studies that reported the outcome with more detail at this time point (DLS; Frennesson 1995; PTAMD bilateral 2009). For PTAMD bilateral 2009, the number of events were calculated applying the percentage estimated from Kaplan-Mayer survival curves to complete cases; Little 1995 and Frennesson 2009 used the last visit at a mean of 3.2 years (Little 1995) and 3.7 years (Frennesson 2009). CAPT and Olk 1999 did not report crude data at two years, but presented survival curves, from which we extracted graphically the proportion of people with CNV and atrophy at two years using the number of eyes followed up in each group to compute standard errors. Most bilateral studies provided marginal data only (i.e. a frequency tabulation that ignores the paired nature of data), but we could extract and use a correlation coefficient from DLS as shown in Appendix 7.

Among bilateral studies, we could extract paired data on development of CNV from Little 1995, but we considered that this study was too small to estimate the correlation coefficient reliably. CAPT provided marginal data, but the P value was obtained from a Cox proportional hazards model, not from a McNemar Chi² test; thus, we did not use the method shown in Appendix 7. There was poor reporting of the primary outcome ‘development of geographic atrophy’. Data from Laser to Drusen Study 1995 were obtained from the authors. Data from survival curves could be estimated from the unilateral arm of CNVPT; cross-tabulations were constructed using the number of complete cases who did not develop CNV because, in the absence of a clear reporting of the total number of eyes at each step of the survival curve, we considered that eyes with a neovascular lesion may have complex fundus changes preventing a precise assessment of geographic atrophy.

Secondary outcomes
Loss of visual acuity was the only secondary outcome that could be extracted for most studies. Particularly, DLS, CAPT, Figueroa 1994, and PTAMD bilateral 2009 presented bilateral data and DLS, Olk 1999, DLS, PTAMD unilateral 2002, and CNVPT presented unilateral data. Most studies provided marginal data, but we could extract a correlation coefficient from Little 1995 and DLS and use it as shown in Appendix 7 to obtain correct standard errors. Frennesson 2009 only reported mean visual acuity and dichotomous data on visual loss could not be obtained. Only CNVPT presented contrast sensitivity and reading ability data.

Most studies analysed drusen reduction. It was possible to extract data on this outcome from two unilateral studies and one bilateral study. For CNVPT, we extracted data graphically from a survival curve using the number of eyes followed up in each group to generate a cross-tabulation of the eyes with a 50% or more drusen area reduction among treated and control eyes. Two studies gave the approximate percentages with apparent drusen reduction: PTAMD unilateral 2002 at 18 months and PTAMD bilateral 2009 at two years. We used the number of participants still followed minus those who developed CNV as the total number in each group for generating the 2 x 2 table. We could not extract data on drusen reduction from the other studies. In fact, CAPT and Little 1995 were bilateral studies but reported marginal data only. Olk 1999 provided pooled data only for unilateral and bilateral cases. Frennesson 1995 provided means and standard deviations but used Snellen values to compute them, which is incorrect, and data had a very skewed distribution. Thus, we decided not to use data from this study. DLS did not report drusen reduction. None of the studies reported quality of life data.

Other comparisons
Olk 1999 also compared subthreshold (i.e. yielding non-visible laser burns) photocoagulation with observation. We obtained marginal data from the bilateral study arm, but no estimate of the intraindividual correlation, together with data from the unilateral study arm.

Excluded studies
See Characteristics of excluded studies table. We excluded four studies: Guymer 2014 was not an RCT; Huang 2011 as the investigator reported that treatment was randomised, but then the participant could choose which eye would receive laser treatment; Sarks 1999, which was a comparative but non-randomised study and Sigelman 1991, which was a case report. Sivagnanavel 2004 and Beaumont 2011 have only been published as an abstract. In particular, Beaumont 2011 treated 121 participants with subthreshold photocoagulation and used the fellow eye as control, finding that drusen disappeared and that there was a small benefit of borderline significance on visual acuity; the contact author reported treatment assignment to either eye was randomised and the study was ongoing and unpublished. We are still trying to contact Sivagnanavel 2004, but have not as yet received further information and so have placed this study under Studies awaiting classification.

Risk of bias in included studies
See ‘Risk of bias’ tables in Characteristics of included studies table and Figure 2.
Figure 2. Methodological quality summary: review authors’ judgements about each methodological quality item for each included study.
Allocation
Slightly more than half of the trials reported adequate methods to generate and conceal the allocation sequence.

Blinding
Participants were not masked (blinded) since a sham procedure was never adopted. We acknowledge that it is not possible to mask outcome assessors to anatomic outcomes because laser scars are visible around the macula, unless subthreshold photocoagulation is used and effective. However, masking of functional outcome assessors can be achieved in theory, but was rarely so, or reported as such, in these studies. We think that development of CNV is a sufficiently objective diagnosis to be classified as having low risk of bias despite lack of masking of outcome assessors. On the contrary, vision outcomes such as visual acuity and contrast sensitivity can easily be measured by a masked assessor, and lack of masking can introduce bias because the procedure is operator dependent.

Incomplete outcome data
Table 1 shows events and non-events of complete cases, number of deaths and number of missing participants in the treatment and control arms. We used these data to assess the impact of incomplete outcome data only in unilateral studies. In fact, in the updated version of this review, we considered missing data as at no risk of bias in bilateral studies because a participant with paired treatment and control eyes is missed.

Figure 3 shows the potential impact of missing data using the method described in Appendix 8. Based on this analysis, only PTAMD unilateral 2002 was at high risk of bias for missing data.
Figure 3. Photocoagulation versus control, outcome: Development of CNV at two years (see CNVPT; Laser to Drusen Study 1995; Olk 1999; PTAMD unilateral 2002). Graphical assessment of the risk of bias due to incomplete outcome data in unilateral studies with missing data reported (see Appendix 8). The minimum and maximum odds ratio change, compared to complete or available cases, is assessed graphically and subjectively taking into account its 95% CI. CI: confidence interval; max: maximum; min: minimum.
Frennesson 2009 was a unilateral study, but we could only obtain the number of events at the end of follow-up (about 3.5 years) and could not extract missing data at two years. Thus, we scored the study at unclear risk of bias for incomplete outcome data.

Selective reporting

Most studies reported the development of CNV and visual acuity, which are the key outcomes in this study, so selective reporting was not a problem in this review.

Other potential sources of bias

One trial was stopped early because an interim analysis suggested a harmful effect of photocoagulation (DLS). The laser producers sponsored three out of four studies using laser subthreshold photocoagulation (Olk 1999; PTAMD bilateral 2009; PTAMD unilateral 2002).

Effects of interventions

See: Summary of findings for the main comparison Summary of findings table: photocoagulation of drusen versus control

Primary outcomes

Development of choroidal neovascularisation

Pooling the results, as seen in Figure 4, showed that photocoagulation did not reduce the development of CNV at two years' follow-up (OR 1.07, 95% CI 0.79 to 1.46, 11 studies, 2159 participants (3580 eyes), high quality evidence; Analysis 1.1). This estimate means that, given an overall occurrence of CNV of 8.3% in the control group, we estimated an absolute risk reduction of no more than 1.4% in the laser group, which is sufficient to exclude a benefit, or an increase of more than 2.8%, which is sufficient to exclude an important harm in this low risk population.

Figure 4. Forest plot of comparison: 1 Photocoagulation versus control, outcome: 1.1 Development of choroidal neovascularisation (two studies provided data on both unilateral and bilateral participants).
A sensitivity analysis assuming moderate correlation (0.5) of the outcome within individuals increased the heterogeneity of bilateral studies to an $I^2$ value of 52%, but Analysis 1.2 shows that the conclusions would not change. Figure 5 presents a graphical exploration of small-study bias in a contour-enhanced funnel plot. In this analysis, we pooled data from bilateral and unilateral studies when they were based on a similar protocol and published simultaneously. Although there were two small studies in the area of larger effect, the lower-left corner of the plot, the Harbord test did not suggest statistical significance of funnel plot asymmetry ($P$ value = 0.444).

**Figure 5.** Contour enhanced funnel-plot investigating small study bias for the primary outcome 'development of choroidal neovascularisation or geographic atrophy'. Shaded areas are areas of statistical significance as explained in the legend.

---

**Development of geographic atrophy**

We could extract data on the development of atrophy from only two small studies (CNVPT; Laser to Drusen Study 1995). Analysis demonstrated no benefit or harm using photocoagulation for development of geographic atrophy (OR 1.30, 95% CI 0.38 to 4.51; Analysis 1.3). The quality of the evidence was low because of imprecision.

One bilateral study presented marginal data on development of geographic atrophy. Specifically, CAPT reported that 1.9% of treated
eyes compared to 1.4% of control eyes of 1008 participants developed atrophy at two years, but due to the paired nature, we could not extract and analyse these data.

**Secondary outcomes**

**Visual acuity**

Four bilateral studies and five unilateral studies allowed the extraction of data on the risk of visual loss of 3 or more lines of visual acuity at two years (a value of 2 or more lines was available in Olk 1999 and PTAMD bilateral 2009) (Analysis 1.4). The analysis demonstrated no benefit or harm with photocoagulation (OR 0.99, 95% CI 0.81 to 1.22). The quality of this evidence was moderate because visual acuity examiners were masked in less than half of studies.

**Contrast sensitivity**

We obtained data on contrast threshold from the authors of Laser to Drusen Study 1995. There was a large uncertainty of the estimates (low quality evidence; Analysis 1.5) and analysis demonstrated no effect of photocoagulation. CAPT also reported on contrast sensitivity, but this was a paired study and the data could not be analysed since an estimate of the correlation coefficient was not obtained. The authors reported marginal data at five years, which indicated that 212/888 (23.9%) treated eyes and 182/887 (20.5%) observed eyes required twice as much contrast (corresponding to a loss of 0.3 log 10 units or more of contrast sensitivity) to read letters.

**Reading ability**

We obtained data on reading speed from the authors of Laser to Drusen Study 1995 for about 50% of the participants included in this small study. Analysis found no statistically significant difference between photocoagulation and observation (low quality evidence due to imprecision; Analysis 1.6). CAPT also reported marginal data on reading ability expressed as critical print size (i.e. the character print’s size below which a person’s reading speed slows down). The authors reported marginal data at five years, which indicated that 260/879 (29.6%) treated eyes and 249/878 (28.4%) observed eyes required a print size twice as large (0.3 LogMAR or 3 lines) or could not read even the largest print size.

**Drusen reduction**

We extracted data on drusen reduction as defined by the investigators from two unilateral studies (CNVPT; PTAMD unilateral 2002), and one bilateral study (PTAMD bilateral 2009), at approximately two years (Analysis 1.7). All three studies found an apparent drusen reduction in treated eyes compared to control eyes with a cumulative OR of 9.16 (95% CI 6.28 to 13.37, 944 eyes, high quality evidence).

Among bilateral studies, others presented marginal data suggesting that photocoagulation caused drusen resorption, but we could not extract these data since an estimate of the within-person correlation was not obtained. Specifically, CAPT found that 34.3% of treated eyes versus 8.6% of control eyes of 1008 participants had a 50% drusen reduction at two years. Frennesson 1994 reported that 29/30 treated eyes versus 2/30 control eyes had drusen reduction, on average after three months. Little 1995 reported that 17/27 treated eyes had drusen resorption by six months compared to 5/27 observed eyes by one year.

Other studies reported data suggesting drusen disappearance using photocoagulation compared to observation, but we could not extract data for various reasons (means and standard deviations suggesting skewed data (Frennesson 1995; Frennesson 2009), pooled data from unilateral and bilateral study arms (Olk 1999), or data not available (DLS)).

**Quality of life**

None of the studies reported quality of life.

**Subgroup analysis**

We conducted subgroup analyses for the primary outcomes only (development of CNV and geographic atrophy).

**Type of laser**

We conducted a subgroup analysis comparing argon, diode and dye laser, pooling data from unilateral and bilateral studies when they had been conducted and reported simultaneously using similar methods. We excluded DLS since it used two types of laser and no separate data were available.

Although there was some subgroup heterogeneity ($I^2 = 97\%$, $P = 0.07$), the $P$ value for subgroup differences did not reach significance ($P = 0.12$), and none of the groups showed a significant increase or decrease of the risk of CNV (Analysis 1.8).

**Visible versus subthreshold photocoagulation**

In the update of this review, we included two more studies adopting subthreshold photocoagulation (Frennesson 2009; PTAMD bilateral 2009). Thus, we could conduct a subgroup analysis comparing visible, standard photocoagulation (eight studies, 2870 eyes) with subthreshold photocoagulation (four studies, 950 eyes) (Analysis 1.9). We could not show statistically significant differences between the two groups ($I^2 = 9\%$, $P = 0.29$) and the OR in the subthreshold group excluded a large benefit (OR 1.27, 95% CI 0.82 to 1.98).
Adverse effects
We considered adverse effects such as development of CNV, development of geographic atrophy and visual loss above. Only one trial formally considered additional adverse effects. They noted that, “There were no reports of burns applied to the fovea avascular zone, breaks in Bruch’s membrane, or haemorrhages at the initial or 1-year treatment” (CAPT).
Olk 1999 noted a juxtafoveal scar in one eye (out of 63 eyes) treated with visible burns.

Potential impact of a new study
As explained in the Data synthesis section, we assessed the potential impact of a new study on the meta-analysis according to Langan 2012. Figure 6 shows that it is unlikely that further research will change the results of this review, since they should be either favourable studies and much larger than those included, or smaller but with favourable effects far exceeding those observed in this review. This is compatible with the fact that no trials were published after 2009.

Figure 6. Potential impact of a new study on the meta-analysis using the command 'extfunnel' in Stata (see Data synthesis and Langan 2012). sig: significant.

DISCUSSION
AMD is a disease characterised by an enormous social burden. The availability of a therapeutic approach able to reduce the incidence of the major complications (i.e. CNV and atrophy) would be extremely welcome. Several authors have recorded that in their experience the use of laser can result in reabsorption of macular drusen (Cleasby 1979; Figueroa 1994; Gass 1973; Wetzig 1994). As yet, it is unclear whether drusen reduction can lead to clinical benefits, including improvement or stabilisation of visual acuity, delayed or reduced CNV, or harms such as the onset of atrophy.
Summary of main results

In the update of this review, we identified two new trials, leading the total number to 11 studies, in which 2159 participants (3580 eyes) were randomised to laser treatment of drusen or observation and followed up to at least two years. These trials confirmed the clinical observation that laser photocoagulation of drusen was able to cause their disappearance. However, there was no evidence that this loss of drusen resulted in any benefit in terms of the development of CNV or geographic atrophy or prevention of visual acuity loss. The results of the present review indicated that the prophylactic laser treatment of drusen is ineffective as a means for delaying the progression of AMD and preventing visual loss. A clinically relevant benefit can be excluded for people at medium risk of CNV, which was about 9% within two years in our primary meta-analysis, based on the primary outcomes. Among the secondary outcomes, the CI of the visual loss outcome also tended to exclude important harms.

The two new studies used near-infrared subthreshold photocoagulation, totalling four studies with 539 eyes of different people treated with this technique. The meta-analytic OR and its 95% CI also did not suggest potential for benefit. However, no study included in this review used micropulse subthreshold photocoagulation, since photocoagulation was used with low power but continuous laser light delivery.

Overall completeness and applicability of evidence

Some of these trials adopted a paired study design (six studies, 1454 participants), which rendered the analysis of the data difficult. Moreover, only a few studies reported data on secondary outcomes, especially contrast sensitivity and reading ability. Despite these limitations, the studies included in this review were conducted in different countries and follow-up length was enough to be able to record long-term effects of this intervention.

Quality of the evidence

Overall, we judged the evidence included for the primary outcome ‘development of CNV’ represent high quality of evidence (i.e. that we are reasonably certain that the estimate of effect represents the true value). We downgraded the judgement of quality to low for the other primary outcome ‘development of geographic atrophy’ because there were only two studies with few participants and, therefore, the effect estimates were very imprecise.

Potential biases in the review process

One source of bias in this review may be the pooling of unilateral and bilateral studies based on assumptions about the statistical correlation of within-person data. To try to counteract this potential shortcoming, we not only used the information available from some studies, suggesting very low correlation for the primary outcome ‘occurrence of CNV’, but also used a mean correlation as a sensitivity analysis, which did not change the conclusions of our review.

Authors’ conclusions

Implications for practice

Even though drusen area reduction can be achieved through laser treatment, this review suggests that this intervention is not associated with improved outcomes for the patients, based on meta-analyses of studies, which, overall, had a low risk of bias.

Implications for research

The results of this review suggest there is no need to conduct more research on photocoagulation directed to drusen in people with AMD, in accordance with the fact that no further trials were published after 2009. We acknowledge that the evidence on different lasers sources and strategies, such as the subthreshold one, is more limited, yet our findings do not seem to differ for this subtype of laser photocoagulation, if it is obtained with low-power continuous laser light, such as in the included studies, which did not use micropulse photocoagulation.

A study is ongoing to investigate the effect of nanosecond laser treatment to drusen.

- Thank you to Barbara S. Hawkins, PhD; Marta M. Gilson, PhD; Susan Vitale, PhD; Neil M. Bressler, MD and Susan B. Bressler, MD for providing unpublished data on the Laser to Drusen Study 1995 study. Also thanks to Dr. Christina Frennesson, Dr. Thomas R. Friberg and Dr. Ying-xiang Huang for providing additional data on included and excluded studies.
- The Cochrane Eyes and Vision Group (CEVG) created and executed the search strategies.
- We thank José María Ruiz-Moreno and Alicja Rudnicka for their comments on this review and Stephen Gichuhì and Barbara Hawkins for their comments on the protocol for this review.
- We gratefully acknowledge the contribution of David Brandon, Harold Burton, Peter Dyson, Jan Elson and Brenda Rogers of the CEVG AMD Consumer Panel for their comments on the abstract and plain language summary.

## Characteristics of included studies

### CAPT

| Methods | Method of allocation: treatment assignments were generated using a randomly permuted block method, stratified by clinical centre and using a randomly chosen block size. A member of the CAPT Co-ordinating Centre reviewed an eligibility checklist with the local ophthalmologist and clinic co-ordinator during a teleconference before disclosing which of the 2 eyes was assigned to laser treatment. Masking: masked VA examiners. Unclear if participants and care providers were masked. Not reported if anatomic outcomes assessors were masked (i.e. Photograph Reading Centre), but masking was unlikely to be achieved since photocoagulation generates visible scars. Exclusions after randomisation: none reported. Losses to follow-up: during 5 years of follow-up, 5891 (97.2%) visits were completed of the 6061 6-month and annual visits scheduled for surviving CAPT participants. This percentage was relatively stable over time. Unusual study design: bilateral or paired study, i.e. 1 eye randomised to treatment or control and the fellow eye to the other study arm. |
| Participants | Country: US. Number randomised: 1052 participants. Enrolment period: May 1999 to March 2001. Age: mean 71 years. Sex: 637 women (60.6%). Inclusion criteria: at least 10 drusen of size $\geq 125 \mu m$ within 3000 $\mu m$ of FAZ centre; BCVA: 20/40 or more; aged $\geq 50$ years. Exclusion criteria: CNV or serous retinal PED in either eyes; geographic atrophy within 500 $\mu m$ of FAZ centre; any ocular disease that might affect VA. |
| Interventions | Treatment: 60 burns in a grid pattern using a 100-$\mu m$ spot size, 0.1-second duration and power to achieve a barely visible lesion. The burns were applied within an annulus between 1500 and 2500 $\mu m$ from the FAZ centre. Control: observation. |
| Outcomes | Primary: loss of $\geq 15$ letters. Secondary: change in VA; change in contrast sensitivity; change in critical print size; incidence of late AMD (CNV, serous PED, geographic atrophy). |
| Notes | Since 2001, the participants were informed of the AREDS results and were left free to consume antioxidants. Supported by the National Eye Institute, Bethesda, Maryland (grant nos: EY012211, EY012261, EY012279). COI declaration: the Manuscript Writing Team had no COI with regard to the material presented in the article. |

<td><strong>Methods</strong></td>
<td>BILATERAL: method of allocation: right eye randomly assigned to either laser treatment or observation. Left eye assigned to alternate treatment. UNILATERAL: random allocation to laser treatment or observation. Stratified by clinical centre and study (bilateral/unilateral) and blocked using a randomly selected block size. Issued over telephone from central location. Masking: participant: no; provider: unclear; outcome: no for fundus features; yes for VA. Exclusions after randomisation: not reported. Losses to follow-up: among participants alive at 12 months, 57/57 were examined in the laser group and 58/61 in the observation group. At 2 years, 46/57 (80.7%) treated eyes compared to 47/58 (81%) control eyes were still followed. However, causes of loss to follow-up other than death were not reported.</td>
<td></td>
</tr>
<tr>
<td><strong>Participants</strong></td>
<td>Country: US in 15 clinical centres. Enrolment period: October 1994 to December 1996. BILATERAL: number randomised: 156 participants (312 eyes). Age: mean 71 years. Sex: 61% women. UNILATERAL: number randomised: 120 participants. Age: mean 73 years. Sex: 63% women in treatment group; 59% women in control group. Inclusion criteria: aged ≥ 50 years with colour stereo photographs and a fluorescein angiogram of both eyes taken within 14 days of enrolment, free of any condition that would preclude 2 years' follow-up. No exudative AMD. Study eye: &gt; 10 large drusen (&gt; 63 µm) within 3000 µm of the FAZ with VA of 20/40 or better and no evidence of current or past CNV. BILATERAL: no exudative AMD in both eyes. UNILATERAL: no evidence of current or past CNV. Exudative AMD in fellow (non-study) eye. Exclusion criteria: evidence of serous PED ≥ 1 MPS disc area, geographic atrophy within 500 µm of the centre of the FAZ, myopia (≥ 8 dioptres spherical equivalent), previous laser treatment to the retina, severe non-proliferative or proliferative diabetic retinopathy or diabetic macular oedema, progressive ocular disease.</td>
<td></td>
</tr>
<tr>
<td><strong>Interventions</strong></td>
<td>Treatment: low-intensity laser treatment. 3 different laser treatment protocols: 1. Laser 20: 20 laser burns, 100 µm in diameter, in a pattern of 3 rows placed between the 12 and 6 o'clock positions beyond the temporal perimeter of the FAZ. The desired intensity of the burns was a grey-white lesion. Direct application of laser burns to drusen to be avoided. Whenever the area of drusen had not been reduced by ≥ 50% at 6 months of enrolment, a second treatment was applied nasal to the fovea in a mirror image of the first treatment. During the last 6 months of enrolment, a second laser treatment protocol was adopted that specified 24 laser burns, 100 µm in diameter in a circular pattern of 2 rows surrounding the macular drusen. Control: observation of fellow eyes.</td>
<td></td>
</tr>
<tr>
<td><strong>Outcomes</strong></td>
<td>VA (EDTRS); contrast threshold (Pelli Robson); reading ability (MN Read charts). Development of CNV, development of geographic atrophy, disappearance of drusen (stereoscopic colour photographs of the macular and disc of each eye and fluorescein angiogram).</td>
<td></td>
</tr>
<tr>
<td><strong>Notes</strong></td>
<td>Enrolment in these pilot studies was suspended after recommendation by the Data and Safety Monitoring Committee (DSMC) because there was a higher incidence of...</td>
<td></td>
</tr>
</tbody>
</table>
CNV within 12 months of study enrolment in laser-treated eyes than in observed eyes, predominantly in the Fellow Eye Study. Furthermore, data from the bilateral study arm were reported at 12 months but not thereafter.

Supported by an unrestricted gift from Research to Prevent Blindness, New York, NY, to the University of Pennsylvania; gifts to the Macular Degeneration Research Fund, Department of Ophthalmology, University of Pennsylvania, Philadelphia, PA; grants from the Macula Foundation, New York, NY; Research Foundation of the University of Pennsylvania, Philadelphia, PA; and Mackall Trust, New York, NY; and grant R21 EY11275 from the National Eye Institute, National Institutes of Health, Bethesda, MD.

COI declaration: none of the authors have a proprietary interest in this study.

</tr>
</tbody>
</table>
Method of allocation: randomisation was conducted with a computerised weighted coin method in the Research and Development office. The randomisation assignment was provided by telephone, and the clinic co-ordinator printed the randomisation assignment on the participant’s baseline form. The clinical investigator was then informed of the randomisation allocation. All study eyes of eligible participants in the UNILATERAL group were randomised. The study eye was randomised to laser treatment or no laser treatment. All right eyes of eligible participants in the BILATERAL group were randomised to laser treatment or no laser treatment; the fellow eye received the alternate treatment.

Masking: participant: unclear; provider: unclear; outcome assessor: masked VA examiner

Exclusions after randomisation: none reported

Losses to follow-up: UNILATERAL: at 3 years, VA was obtained in 73/92 (80.7%) laser-treated eyes vs. 66/85 (77.6%) control eyes. Development of CNV was recorded in 91/92 treated eyes and 85/85 control eyes. BILATERAL: VA obtained in 72/105 participants at 3 years, and CNV development assessed in 103/105 eyes at 3 years.

Unusual study design: some participants had both eyes randomised (BILATERAL group) and within-person correlation was taken into account.

Participants

Country: UK
BILATERAL: number randomised: 105 participants (210 eyes). Age: 70.1 years (range: 52 to 100). Sex: 31 men/74 women
UNILATERAL: number randomised: 177 participants. Age: 72 years (range: 54 to 87). Sex: 80 men/97 women

Inclusion criteria: drusen with/without focal RPE hyperpigmentation in the study eye and CNV in the fellow eye; BCVA at least 6/12 (20/40); aged at least 50 years

Exclusion criteria: geographic atrophy in either eye; any other eye disease able to influence VA; allergy to fluorescein

Interventions

Treatment: argon green/yellow dye laser with 200-µm spot size, 0.2 second duration and the lowest energy to produce a very faint burn; overall 12 burns: 4 burns placed 750 µm from FAZ centre (12, 3, 6, 9 o’clock), and 8 burns 1500 µm from FAZ centre (12, 1.30, 3, 4.30, 6, 7.30, 9, 10.30, 12 o’clock); drusen treated directly if they were coincident with protocol treatment allocation

Control: observation

Outcomes

Proportion of participants who developed CNV; VA

Notes

Protocol of treatment revised after 23 months: 12 burns (0.2 seconds to 200-µm spot size) placed in circular pattern at 1000 µm from FAZ centre

Supported in part by Deutsche Forschungsgemeinschaft (DFG GR 1007/3-1 and Ho 1926/1-2) and the Deutsche Akademischer Austauschdienst ARC IX-95/32 (MG)

### Frennesson 1995

#### Methods
- Method of allocation: not reported; in 5 participants with both eyes eligible the eye with better VA was randomised
- Masking: participant: unclear; provider: unclear; outcome: unclear
- Exclusions after randomisation: none reported
- Losses to follow-up: 2/19 participants in the treated group vs. 0/19 in the control group lost to follow-up at 3 years
- Unusual study design

#### Participants
- Country: Sweden
- Number randomised: 38 participants
- Age: 71.6 years (SD 6.5) treated participants; 68.5 years (SD 6.2) control participants
- Inclusion criteria: soft drusen; VA at least 0.8
- Exclusion criteria: CNV, PED, pigmentary clumping, macular atrophy, haemorrhage, any other eye disorder that could affect VA

#### Interventions
- Treatment: argon green laser with 200-µm spot size, 0.05 seconds' duration, power to produce a barely visible lesion. Treatment with a temporal horse shoe-shaped area extending to the vascular arcades, with direct treatment of the drusen
- Control: observation
- Duration: 3-8 years

#### Outcomes
- Anatomic: mean drusen area, development of CNV
- Functional: Snellen VA; colour vision (Farnsworth panel D-15); central visual field (Humphrey 10-2)

#### Notes
- The study was supported by grants from the Swedish Medical Research Council (Project No 12X-734), from the Research Committee of the County of Östergötland and from Synfrämjandet’s Research Foundation
- COI declaration: not reported

### Allocation concealment (selection bias)

| High risk |

Randomisation was delivered from Linköping University Hospital. Enrolling doctors were not masked to treatment allocation.

### Blinding (performance bias and detection bias)

| Low risk |

Participants masked and doctors unmasked, but CNV occurrence was sufficiently objective as a diagnosis to be considered unbiased.

### Blinding (performance bias and detection bias)

| High risk |

Care providers were unmasked. Participants could not be masked since no sham procedure was mentioned.

### Incomplete outcome data (attrition bias)

| Low risk |

Mean follow-up time was about 3.5 years and two-thirds of participants were followed up to 4 years, with losses balanced across groups. Study authors reported causes of missingness were death or illness in 5 of 6 cases at 2 years.

### Selective reporting (reporting bias)

| Low risk |

Main relevant outcome measure were reported.

### Other bias

| Unclear risk |

Unclear.

---

**Laser to Drusen Study 1995**

**Methods**

- Method of allocation: computer-generated randomisation list with randomly selected block sizes.
- Allocation groups: observation vs. laser (1 : 1), laser further divided (1 : 1) in temporal vs. nasal and temporal treatment.
- Masking: participant: unclear; provider: unclear; outcome: unclear.
- Exclusions after randomisation: none reported.
- Losses to follow-up: 7/47 (15%) of treatment group and 10/52 (19%) of control group seen at 2 years.

**Participants**

- Country: US.
- Number randomised: 99 participants.
- Age: mean 74 years (SD 6.6), range 55 to 84 years.
- Sex: 69.7% women.
- Inclusion criteria:
  - large drusen (> 63 µm in diameter) and focal hyperpigmentation, and no neovascular AMD in 1 eye only (study eye).
  - evidence of neovascular AMD (CNV, disciform scar, laser scar for CNV) in 1 eye only (fellow eye).
  - VA 20/40 or better in study eye (other information says 20/50 or better).
  - no significant co-existing ocular disorder in study eye.
  - aged ≥ 50 years.
Exclusion criteria:
- history of laser surgery or vitreous surgery in study eye
- low probability of completing 2-year follow-up schedule (poor health, live far from clinical centre, unwilling to return)
- geographic atrophy within 3000 μm of foveal centre
- other conditions associated with CNV, including pathological myopia (spherical equivalent exceeding -8.00 dioptres or clinical evidence of lacquer cracks), angiod streaks, histo spots, pattern dystrophies of RPE, etc. in study eye
- severe non-proliferative or worse diabetic retinopathy or diabetic macular oedema in study eye
- other progressive ocular disease that could impair VA such as glaucoma in the study eye
- lensectomy or intraocular lens implantation within 3 months

Interventions
Laser wavelength: dye yellow laser (577 nm) or infrared diode (very early - was discontinued). Number of burns: various, 2 scatter patterns described below; spot size: 50 μm; duration: 0.1 seconds; intensity: very light grey burn (just visible); no treatment within 500 μm of foveal centre and beyond 3000 μm from foveal centre; scatter burns approximately 2-3 burn widths apart, trying to avoid placing burns directly over focal clumps of hyperpigmentation. Do not have to place directly on drusen, but in placing scatter, small placement changes (< 50 μm) should be done to centre spot on drusen
Pattern 1: (temporal = 180 degree) - not placed in nasal portion of macula (vertical line intersects foveal centre)
Pattern 2: (temporal and nasal = 360 degree) - burns placed in scatter both nasal and temporal portion of macula (exclusive of central macula within 500 μm of foveal centre and not beyond 3000 μm of foveal centre)

Outcomes
Development of CNV; VA; information on other outcomes not available

Notes
Randomisation changed - originally 1:1 (laser vs. observation), then laser group randomised 1:1 (infrared diode vs. yellow dye) - each colour laser was randomised 1:1 (temporal vs. temporal and nasal)
The red diode laser arm was stopped early (probably December 1995)
Pilot study nature - so some clinical centres did not do all tests (reading, contrast) - not all clinical photographs graded
Funding source unknown

### Olk 1999

#### Methods

- **Method of allocation:** not reported; BILATERAL: 1 eye was assigned to treatment and 1 eye to observation. UNILATERAL: 1 eye eligible that eye was assigned to either treatment or observation. BILATERAL/UNILATERAL: eyes assigned to treatment were further randomised to either ‘visible’ or ‘subthreshold’ treatment.
- **Masking:** participant: unclear; provider: unclear; outcome: unclear.
- **Exclusions after randomisation:** 25/152 participants (35 eyes) were enrolled initially in the pilot study but subsequently determined to be ineligible for various reasons, mainly violation of inclusion criteria.
- **Losses to follow-up:** at 24 months, 33 eyes had missed visits: 9 eyes (4 observation, 2 visible, 3 subthreshold) were in deceased participants, 14 eyes were in the observation group, and 10 eyes were in the treatment group (5 eyes, visible; 5 eyes, subthreshold).
- **Unusual study design:** some eyes

#### Participants

- **Country:** US
- **Number randomised:** BILATERAL: 77 participants (154 eyes) with both eyes eligible. UNILATERAL: 75 participants (75 eyes) with 1 eye eligible (unilateral study arm), that eye was assigned to either treatment or observation.
- **Enrolment period:** July 1994 to June 1996.
- **Sex:** 152 participants enrolled; 57 men, 95 women.
- **Age:** mean 74.5 years, range 54-88 years.
- **Inclusion criteria:** aged > 50 years; diagnosis of AMD with ≥ 5 large (≥ 63 µm), soft drusen within 2250 µm of the centre of the FAZ in both eyes (bilateral study arm) or in 1 eye (unilateral study arm) if the fellow eye had evidence of exudative AMD; and VA of ≥ 20/63 on the ETDRS chart in all eligible eyes.
- **Exclusion criteria:** exudative macular degeneration in either eye for bilateral participants and in both eyes for unilateral participants; other ocular diseases.

#### Interventions

- **Eyes were treated with a slit-lamp integrated diode photocoagulator using 810-nm wavelength (IRIS Medical OcuLight SLx; Iridex Corp., Mt. View, CA).**
- **48 diode laser lesions of 125 mm were applied in 4 concentric circles outside the FAZ in a scatter or grid pattern between 750 and 2250 mm from the centre of the fovea. Test spot laser lesions were applied to the retina nasal to the optic nerve using 200-millisecond duration, and the power was increased to produce a mild grey lesion (visible burn).**
- **For eyes assigned to visible treatment, this intensity was then applied in a grid pattern as described above.**
- **For eyes assigned to subthreshold treatment, the energy needed for the visible test burn was kept constant, but the duration was halved to 100 milliseconds and treatment then carried out. Only 1 laser treatment was applied to each eye throughout the duration of the study.**

#### Outcomes

- **Anatomic:** reduction of drusen, development of CNV.
- **Functional:** VA.
### Notes

Within-person correlation of outcomes in the bilateral arm not analysed and reported.

Supported in part by grants from IRIS Medical, Mountain View, CA (producer of the laser used in the study), and The University of Pittsburgh Eye and Ear Foundation, Pittsburgh, PA.

COI declaration: not reported.

## PTAMD bilateral 2009

### Methods

Method of allocation: study eyes were assigned randomly to either treatment or observation by a computer-generated, centre-specific, variable block size randomisation at a 1:1 ratio. These random assignments were concealed in opaque envelopes that were opened only upon enrolment of an eligible person who gave consent.

Masking: participant: unclear; provider: unclear; outcome: unclear.

Participant: 1278 eyes of 639 participants.

Outcome: development of CNV and change in best-corrected VA.

Exclusions after randomisation: none reported.

Losses to follow-up: 374/639 (54.3%) participants followed to 2 years.

Unusual study design: paired study.

### Participants

Country: US.

Number randomised: 1278 eyes of 639 participants.

Mean age: 73.0 years (SD 2.5).

Inclusion criteria: aged \(\geq\) 50 years. Eligible eye must have had BCVA of \(\geq\) 20/63 on the ETDRS chart in both eyes; AMD with \(\geq\) 5 drusen that were \(\geq\) 63 \(\mu\)m in diameter and were located within 2250 \(\mu\)m of the centre of the fovea; unilateral participants must have had 1 eye ineligible due to vision loss that was attributed to advanced AMD.

Exclusion criteria: other ocular disease causing visual loss.

### Interventions

Eyes randomised to treatment received a single-session treatment of a grid of 48 diode laser lesions of 125 \(\mu\)m in diameter. Laser treatment was applied in an annular grid that extended from 0.5 (750 \(\mu\)m) to 2.0 (3000 \(\mu\)m) disc diameters from the centre of the FAZ. A slit lamp-based diode laser photocoagulation system (IRIS Medical, Mountain View, CA) emitting energy at 810 nm was used to deliver the laser treatment. Laser lesions were placed in a subthreshold manner by first delivering test spot(s) of 200-millisecond duration placed outside of the macula at a low power (e.g. 200 mW) and then incrementally increasing the power in small (50 mW) increments until a faint grey (threshold) lesion could be detected visually through the treatment lens. While the power setting was left unchanged, the pulse duration was reduced to a 100-millisecond interval to achieve an invisible subthreshold lesion. Laser lesions were then scattered within the annular grid as defined above, beginning by placing 12 spots in a given quadrant and then proceeding to adjacent quadrants to complete the treatment pattern. The drusen were not targeted specifically or preferentially. If a visible lesion was produced while the annular grid treatment was performed, the power setting was reduced to achieve subthreshold lesions with the remainder.

### Outcomes

Anatomic: drusen reduction, development of CNV. Functional: VA.

### Notes

Supported by IRIDEX Corporation, Mountain View, CA (the producer of the laser used in the study); the Eye and Ear Foundation of Pittsburgh, Pittsburgh, PA; Research to Prevent Blindness, Inc., New York, NY and unrestricted funds from several participating centres.

COI declaration: the authors had no financial or proprietary interest in the materials presented.

PTAMD unilateral 2002

### Methods

Method of allocation: study eyes were assigned randomly to either treatment or observation by a computer-generated, centre-specific, variable block size randomisation at a 1:1 ratio. These random assignments were concealed in opaque envelopes that were opened only upon enrolment of an eligible person who gave consent.

Masking: participant: unclear; provider: unclear; outcome: unclear

Exclusions after randomisation: not reported

Losses to follow-up: at 1 year, 184/244 (75%) participants followed (5 deaths), 92 treated eyes and 99 control eyes followed. At 3 years, 124/244 (51%) participants followed (20 deaths), 64 treated eyes and 55 control eyes followed.

Unusual study design: another arm of the study included participants with both eyes eligible, but this report deals with unilateral participants only.

### Participants

Country: US

Number randomised: 244 participants

Age: mean 75.4 years for treated participants, 75.1 years for observed participants

Gender (% women): 59.3 treated participants, 61.5 observed participants

Inclusion criteria: aged ≥ 50 years. Eligible eye must have had BCVA of ≥ 20/63 on the ETDRS chart; AMD with ≥ 5 drusen that were 63 µm in diameter and were located within 2250 µm of the centre of the fovea; unilateral participants must have had 1 eye ineligible due to vision loss that was attributed to advanced AMD

Exclusion criteria: other ocular disease causing visual loss

NCT01790802

Trial name or title
Laser Intervention in Early Age-Related Macular Degeneration Study (LEAD)

Methods
Randomised controlled trial

Participants
Inclusion criteria:
- Men or women aged 50-95 years at the time of consent
- BCVA of 6/12 (20/40) or better in each eye
- Bilateral high-risk early AMD: at least 1 druse ≥ 125 µm within an inner macular zone (a circle with a radius of 1500 µm centred on the fovea) with or without pigment
- A MAIA static threshold sensitivity < 25 dB at any point, within a customised grid, as measured using a MAIA device), at the same location of the 1 eye on 2 separate occasions
- Pupil dilation of ≥ 5 mm in each eye
- Fundus photographs, OCT and FAF images of adequate quality as assessed by the LEAD Image Reading Centre
- Ability and willingness to consent, and be randomised, to the 2RT active or sham laser treatment, and all qualification and follow-up phases of the study

Exclusion criteria:
- Any evidence of definite geographic atrophy within the macula (a circle with a radius of 3000 µm centred on the fovea). Geographic atrophy is defined as an area of partial or complete depigmentation of the RPE in the fundus photographs that has at least 2 of the following 3 characteristics: roughly round or oval shape, sharp margins and visibility of underlying large choroidal vessels.
- Any black (hypofluorescent) area of FAF consistent with GA (roughly round or oval shape, sharp margins), and corroborated on colour photography as a patch of hypopigmentation
- Any evidence of ‘preclinical atrophy’ as determined on OCT: loss of the outer retina (RPE and photoreceptors on the cube scan (Spectralis OCT) (49 horizontal B scans, 120 µm apart over a 20 x 20 degree scan). This covers approximately 6 x 6 mm in an emmetropic eye (note: peri-papillary atrophy further than 1500 µm from the fovea is allowed)
- Current CNV, or past evidence of CNV in either eye.
- Any other experimental treatment for AMD, excluding dietary supplements, received in the past 12 months or thought likely to chronically change the course of the participant’s retinal disease
- Any OCT showing evidence of intraretinal fluid, or subretinal fluid for which CNV cannot be excluded as a cause
- A subfoveal pigment epithelial detachment/drusenoid detachment > 1000 µm in diameter
- Other macular disease with subretinal deposits not typical of AMD, e.g. Malattia Leventinese, Sorsby...
### Interventions

**Experimental:** active laser
- Twelve 2RT nanosecond laser shots in 2 arcs of 6 shots superiorly and 6 shots inferiorly, inside the retinal vascular arcades at an approximate distance from the fovea of 3000 μm, with approximately 1 laser spot diameter between them.

**Sham comparator:** sham laser procedure. To simulate laser application the maximum illumination button will be briefly pressed by the operating physician at each of the 12 locations described above where and when the laser would normally be applied. The laser remains in standby mode preventing accidental laser firing.

### Outcomes

**Primary outcomes:**
- progression to advanced AMD in the treated eye (time frame: 36 months)
- rate of progression to advanced AMD, either CNV, geographic atrophy or preclinical atrophy, in the study eye of treatment group compared to the sham procedure group

**Secondary outcomes:**
- progression to advanced AMD in the untreated eye (time frame: 36 months), rate of progression to advanced AMD, CNV, GA or preclinical atrophy in the fellow (untreated) eye

**Other outcomes:** reversal of early clinical indicators of AMD (time frame: 36 months), reversal of early clinical indicators of AMD (drusen area)
- Improvements in visual acuity (time frame: 36 months)

### Starting date

- Estimated enrolment: 250
- Study start date: November 2011
- Estimated study completion date: June 2017
- Estimated primary completion date: June 2017 (final data collection date for primary outcomes)
NCT01790802 (Continued)

The assessment of the risk of bias due to incomplete outcome data is based on the graphical presentation in Figure 6 based on the methods described in Appendix 8. In the updated version of this review, we considered missing data as at no risk of bias in bilateral studies because a participant with paired treatment and control eyes is missed.

F: failures (choroidal neovascularisation development), S: successes, D: deaths, M: missing of unknown cause, NA: not available.

1 Only last visit follow-up available and no information on when choroidal neovascularisation developed in cases with event.

2 Deaths were not reported and all missing data were coded as missing of unknown cause.

3 Deaths were provided overall (n = 11 at 2 years) and were equally split between assignment groups. Data at 1 or 3 years were available and midpoints were used.

Appendix 7. Estimate of the correlation coefficient of the measurements within participants in bilateral studies

Elbourne 2002 provided a method for conducting meta-analyses of studies using paired data, such as cross-over studies or studies on paired organs. In this appendix, we showed how we adjusted the marginal measurements, that is, with eyes as the unit of analysis extracted from bilateral studies by the intraindividual correlation coefficient extracted from other studies in order to obtain correct standard errors of the odds ratio.

We found both marginal and paired analyses in DLS. Data were limited to the primary outcome ‘development of choroidal neovascularisation (CNV)’ and to the secondary outcome ‘loss of visual acuity’. In particular, Table 4 in DLS presented marginal data on CNV occurrence, our primary outcome, and visual loss while displaying P values obtained with the McNemar test, which is based on the Chi² distribution and is adequate for paired data. In particular, 12/103 laser-treated eyes and 7/103 fellow eyes developed CNV and the McNemar P value was 0.2253. The marginal P value using the Chi² test would have been 0.2286. We considered that the ratio of the z-values corresponding to these paired and marginal P values (1.2039 (paired) and 1.1907 (marginal)) could be used to adjust the standard errors of the marginal logOR of CNV occurrence for laser-treated eyes compared to controls. The inverse ratio of these two z-values was 0.9782, implying that no adjustment of the marginal logOR standard error was needed for the DLS data. Because the marginal logOR variance was 0.4976, its value adjusted for the correlation between eyes was 0.4867, the difference between the two being twice the covariance (which was 0.0054). From these data, the correlation coefficient could be calculated to be only 0.0451 (i.e. 0.0054*sqrt(12*7*96*91)/103, using the method shown in Elbourne 2002). An issue concerning this correlation coefficient imputation is whether the coverage achieved by the McNemar test is acceptable given the possibility of cells with counts close to nil in paired 2 x 2 tables from medium size studies such as this when events are not common.

Given the negligible effect of the correlation between eyes of the same participant for the CNV development outcome in DLS, we used marginal data from bilateral studies as if eyes were independent units.

Using the same method for visual acuity loss, the ratio of the marginal and paired logOR standard errors was 0.8143, resulting in a correlation coefficient of 0.2290. Therefore, for this outcome, we decided to use the inverse variance method and adjust the marginal logOR standard error by 1.2280 (the reciprocal of the previous ratio).

We obtained a different estimate of the correlation between eyes for the CNV outcome from Little 1995. Using the formulas provided by Elbourne 2002, the correlation coefficient was 0.69 in this small data-set using the last follow-up examination to assess the risk of CNV occurrence. Using Elbourne 2002 notations, the numbers to calculate this value would be: \( s = 23, t = 2, u = 0, v = 2 \), hence \( a = 25, b = 23, c = 2, d = 4 \). However, this was a very small study and was expected to estimate correlation imprecisely and also to be affected by approximations due to low cell counts, for which common formulas for 2 x 2 tables do not hold. Thus, we did not use this type of estimate of the correlation coefficient.

Finally, we decided to conduct a sensitivity analysis for the outcome ‘development of CNV’ using a moderate correlation between eyes of 0.5 to correct standard errors of the marginal odds ratio.

Appendix 8. Methods used to deal with incomplete outcome data

We used the following approaches to take into account the impact of missing data. In the updated version of this review, we considered missing data as at no risk of bias in bilateral studies because a participant with paired treatment and control eyes is missed. Thus, we only considered losses in unilateral studies.

We used Stata 13.1 software (StataCorp 2013) users’ written function ‘metamiss’ assuming random uncorrelated opposite informative missingness odds ratios (IMORs) for treatment and controls (1/2 and 2; 2 and 1/2). We assumed additional uncertainty about log(IMOR) by setting its prior standard deviation at 1, which will result in larger 95% confidence intervals and, finally, in less weight on studies with numerous missing data. Finally, we assumed uncorrelated IMORs of treatment and control groups when setting the ‘metamiss’ command. White 2008 provides the underlying theory and a link to download ‘metamiss’.

The results of these sensitivity meta-analyses on the primary analysis occurrence of CNV are shown and discussed in unilateral studies.

DIFFERENCES BETWEEN PROTOCOL AND REVIEW

The protocol was originally published in 2007 and since that time there have been considerable developments in Cochrane methodology including assessment of risk of bias and preparation of 'Summary of findings' tables and grading of the overall quality of evidence using GRADE. We have incorporated these developments in the review.

We have also made the following specific changes from the protocol.

• In the protocol, drusen reduction was planned to be evaluated considering the number of eyes showing at least a 50% reduction of drusen area from the baseline aspect. However, data were sparsely reported and, therefore, we modified the protocol to allow an extraction based on the investigators’ definition.

• In the protocol, we planned to use the risk ratio as the main effect measure but we used the odds ratio because this made it easier to adjust for within-person correlation. See section ‘Measures of treatment effect’.

• In the 2015 update, we decided that the risk of bias due to missing data was low in bilateral trials, since a pair of treatment and control eyes would be lost, which would be unlikely to alter the odd ratio significantly. Thus, we simplified the sensitivity analysis of missing data as described in Appendix 8.

INDEX TERMS

Medical Subject Headings (MeSH)
Disease Progression; Geographic Atrophy [prevention & control]; Laser Coagulation [methods]; Macular Degeneration [*prevention & control]; Randomized Controlled Trials as Topic; Retinal Drusen [complications; *surgery]; Visual Acuity
