Haemostatic drugs for traumatic brain injury (Review)  
Copyright © 2010 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.
**ABSTRACT**

**Background**

Traumatic brain injury (TBI) is a leading cause of death and disability. Intracranial bleeding is a common complication of TBI, and intracranial bleeding can develop or worsen after hospital admission. Haemostatic drugs may reduce the occurrence or size of intracranial bleeds and consequently lower the morbidity and mortality associated with TBI.

**Objectives**

To assess the effects of haemostatic drugs on mortality, disability and thrombotic complications in patients with traumatic brain injury.

**Search methods**

We searched the electronic databases: Cochrane Injuries Group Specialised Register (3 February 2009), CENTRAL (*The Cochrane Library* 2009, Issue 1), MEDLINE (1950 to Week 3 2009), PubMed (searched 3 February 2009 (last 180 days)), EMBASE (1980 to Week 4 2009), CINAHL (1982 to January 2009), ISI Web of Science: Science Citation Index Expanded (SCI-EXPANDED) (1970 to January 2009), ISI Web of Science: Conference Proceedings Citation Index - Science (CPCI-S) (1990 to January 2009).

**Selection criteria**

We included published and unpublished randomised controlled trials comparing haemostatic drugs (antifibrinolytics: aprotinin, tranexamic acid (TXA), aminocaproic acid or recombined activated factor VIIa (rFVIIa)) with placebo, no treatment, or other treatment in patients with acute traumatic brain injury.

**Data collection and analysis**

Two review authors independently examined all electronic records, and extracted the data. We judged that there was clinical heterogeneity between trials so we did not attempt to pool the results of the included trials. The results are reported separately.

**Main results**

We included two trials. One was a post-hoc analysis of 30 TBI patients from a randomised controlled trial of rFVIIa in blunt trauma patients. The risk ratio for mortality at 30 days was 0.64 (95% CI 0.25 to 1.63) for rFVIIa compared to placebo. This result should be considered with caution as the subgroup analysis was not pre-specified for the trial. The other trial evaluated the effect of rFVIIa in 97 TBI patients with evidence of intracerebral bleeding in a computed tomography (CT) scan. The corresponding risk ratio for mortality...
at the last follow up was 1.08 (95% CI 0.44 to 2.68). The quality of the reporting of both trials was poor so it was difficult to assess the risk of bias.

Authors’ conclusions

There is no reliable evidence from randomised controlled trials to support the effectiveness of haemostatic drugs in reducing mortality or disability in patients with TBI. New randomised controlled trials assessing the effects of haemostatic drugs in TBI patients should be conducted. These trials should be large enough to detect clinically plausible treatment effects.

PLAIN LANGUAGE SUMMARY

Haemostatic drugs for traumatic brain injury

Injury (also called trauma) is a leading cause of death for children and young adults. Traumatic brain injury, such as from a blow to the head, is a frequent cause of death for patients with trauma who survive to reach hospital. Approximately half of patients with traumatic brain injury develop bleeding into the brain within the first 48 hours of hospital admission. If bleeding occurs, accumulating blood within the skull can put pressure on the brain and this may be fatal or result in serious long-term disability for the patient. Therefore, drugs that promote the production of clots or reduce the destruction of existing clots (known as haemostatic drugs) might reduce the bleeding into the brain after an injury and thereby reduce the risk of death or disability.

We searched for randomised clinical trials looking at the effectiveness of haemostatic drugs for reducing mortality and disability in patients with traumatic brain injury. We found two studies that evaluated the effects of a type of haemostatic drug called recombinant activated factor VII. We reviewed the data presented in the reports of these trials. Both trials were too small to confirm or refute any plausible clinical effect, so we were unable to reach any conclusions regarding the effectiveness of haemostatic drugs for traumatic brain injury patients. More trials are needed to answer this question. Future trials should be large enough to detect plausible and important clinical effects.

BACKGROUND

Description of the condition

Traumatic brain injury is one of the main causes of death in patients with injuries, and is a leading cause of death and disability in young people (Ghajar 2000). Every year approximately 1.5 million people die and at least 10 million people are killed or hospitalised because of a traumatic brain injury (Langlois 2006). The incidence, fatality and disability rates are higher in low- and middle-income countries than in high-income countries (Hyder 2007).

Although much of the damage to the brain occurs at the time of the injury, secondary brain damage due to ongoing intracranial bleeding and brain swelling is an important and potentially avoidable cause of morbidity and mortality. Intracranial bleeding is a common complication of traumatic brain injury. In the CRASH trial, which included patients with mild, moderate and severe traumatic brain injury, 56% of trial participants had at least one intracranial bleed that could have been epidural, subdural, subarachnoid or intra-parenchymal (CRASH Trial).

There is evidence that intracranial bleeding can develop or worsen after hospital admission. Prospective observational studies have shown that traumatic intracranial haemorrhage expansion occurs in up to 51% of patients with traumatic brain injury during the first 24 to 48 hours after hospital admission (Narayan 2008). Prognostic studies have shown that intracranial haemorrhage is associated with increased mortality and disability six months after injury (Maas 2007; Perel 2008). Intracranial bleeding exerts significant pressure on brain tissue (Bullock 2006), and prompt neurosurgical intervention is an important part of the therapeutic approach. However, not all intracranial haemorrhages can be controlled by surgical intervention and there is interest in pharmacological approaches that use haemostatic drugs to reduce the occurrence or size of intracranial bleeds (Ceylan 1992; Mandera 1999; Holcomb 2004).
Description of the intervention

Haemostatic drugs have the potential to reduce bleeding by influencing the coagulation cascade. In the haemostatic process, coagulation occurs rapidly to build a tight net of fibrin at the site of the damaged vessel. At the same time, the fibrinolytic system removes fibrin deposits that could cause permanent occlusion of blood vessels once vascular repair has taken place (Prentice 1980). Thus, the coagulation and fibrinolytic systems are in a state of dynamic balance that maintains an intact vascular system. The treatments that have been most extensively evaluated as haemostatic drugs include antifibrinolytics and pro-coagulant drugs such as recombinant activated factor VII (rFVIIa) (Mannucci 2007). Antifibrinolytic drugs maintain the stability of blood clots, whereas pro-coagulant drugs act directly on the coagulation cascade (Holcomb 2004).

The pro-coagulant rFVIIa acts locally at the site of tissue injury. It is believed that it binds to exposed tissue factor and generates thrombin, which activates the platelets. The activated platelet surface forms a template on which recombinant factor VIIa can directly or indirectly mediate further activation of coagulation, resulting in the generation of more thrombin and, ultimately, in the conversion of fibrinogen to fibrin. Antifibrinolytic agents suppress fibrinolysis, thereby reducing excessive or recurrent bleeding. Antifibrinolytics can be divided into lysine analogues (tranexamic acid (TXA) and aminocaproic acid) and plasmin inhibitors (aprotinin). The former impairs endogenous fibrinolysis by blocking lysine binding sites on plasminogen molecules. In contrast, aprotinin directly inhibits the fibrinolytic enzyme plasmin, plasma and tissue kallikrein, trypsin and activated coagulation factor XII.

How the intervention might work

Haemostatic drugs have been used to prevent or reduce blood loss and the need for blood transfusion. For example, antifibrinolytic drugs are widely used in general surgery to reduce bleeding and the need for transfusions (Slaughter 1997). A systematic review of the use of antifibrinolytic agents in surgical patients identified 21 randomised controlled trials that included 20,781 participants (Henry 2007). The results showed that TXA reduced the risk of blood transfusion by 39% (risk ratio (RR) 0.61, 95% confidence interval (CI) 0.54 to 0.69), while aprotinin lowered the risk by 34% (RR 0.66, 95% CI 0.61 to 0.71). Antifibrinolytic agents also reduced the need for blood transfusion and reoperation due to bleeding. There was a trend toward a decreased risk of death in patients treated with aprotinin (RR 0.90, 95% CI 0.67 to 1.20) and TXA (RR 0.60, 95% CI 0.32 to 1.12) but this was not statistically significant. There was no evidence of an increased risk of thrombotic events with either treatment.

The effects of haemostatic drugs in non-traumatic intracranial bleeding have also been evaluated. A systematic review of randomised controlled trials of antifibrinolytic drugs in patients with aneurysmal subarachnoid haemorrhage showed that antifibrinolytic drugs reduced the rate of re-bleeding by approximately 40% but, because of the associated increase in cerebral ischaemia, there was no overall benefit (Roos 2003). However, the length of treatment in these trials was six weeks. It is possible that a shorter treatment period might prevent re-bleeding without increasing the risk of ischaemia. The systematic review was conducted in 2003. Since then, a randomised controlled trial of early administration of a short course (three days) of TXA in patients with aneurysmal subarachnoid haemorrhage has found that TXA reduced the occurrence of re-bleeding from 10.8% to 2.4%, with no evidence of increased side effects (Astrup 2006).

A systematic review of haemostatic drugs in primary intracerebral haemorrhage (non-traumatic) found four phase II trials and reported that haemostatic drugs reduced the risk of death and dependence measured on the modified Rankin Scale (RR 0.79, 95% CI 0.67 to 0.93) and the Glasgow Outcome Scale (RR 0.90, 95% CI 0.81 to 1.01) (You 2006). A recent clinical trial, which was not included in that systematic review, showed that activated factor VIIa reduced intracerebral haemorrhage expansion but did not improve the survival or functional outcomes of patients (Mayer 2008).

Why it is important to do this review

If haemostatic agents reduce intracranial bleeding in patients with traumatic brain injury, they could substantially reduce the extent of secondary brain damage and subsequently lower the mortality and morbidity rates associated with brain injury. Given the number of cases of traumatic brain injury that occur each year, even a modest reduction in the risk of unfavourable outcomes could have major public health implications.

OBJECTIVES

To assess the effects of haemostatic drugs on mortality, disability and thrombotic complications in patients with traumatic brain injury.

METHODS

Criteria for considering studies for this review

Types of studies
We included published and unpublished randomised controlled trials comparing haemostatic drugs with placebo, no treatment, or other treatment in patients with acute traumatic brain injury. Comparisons between different types of haemostatic drugs were also to be included.

Types of participants
Any patient with traumatic brain injury.

Types of interventions
Any of the systemic haemostatic drugs listed below compared with placebo, no treatment, or another haemostatic drug. For studies in which different doses of the intervention were compared with placebo, the intervention groups were combined and compared with the control group. For the purpose of this review, we considered the following haemostatic drugs.
- Antifibrinolytics: aprotinin, tranexamic acid (TXA), aminocaproic acid.
- Activated factor VIIa.

Types of outcome measures

Primary outcomes
1. Mortality
2. Disability (Glasgow Outcome Scale (GOS), Disability Rating Scale (DRS), or other measure of neurological function)
3. Thrombotic complications: deep venous thrombosis (DVT), pulmonary embolism (PE), stroke, and myocardial infarction (MI)

Secondary outcomes
1. Volume of intracranial bleeding
2. Brain ischaemic lesions
3. Need for neurosurgical operation or reoperation
4. Renal failure

Searching other resources
We searched the Internet for relevant information and conference abstracts. We also sought other potentially relevant published, unpublished, or ongoing studies by:
1. checking the reference lists of relevant papers and literature reviews,
2. communicating with relevant trial authors,
3. contacting the manufacturers of relevant drugs.

Data collection and analysis

Selection of studies
Two review authors (PP and IR) independently examined all electronic records and their abstracts to establish eligibility. They decided on whether or not to acquire the full report and, in cases of uncertainty, obtained the full report. We planned to resolve any disagreements through discussion and consultation with a third review author. Any duplicate trials were planned to be examined individually to verify that they presented unique sets of data. If we were unsure about whether a study should be included, because additional information was necessary, we allocated the study to the list of those awaiting assessment and contacted the study authors for clarification. The reasons for excluding studies are described in the 'Characteristics of excluded studies' table.

Data extraction and management
Two review authors (PP and IR) extracted the data from the included studies. We extracted data on the study methods, participants, interventions, and outcomes. We extracted data so that an intention-to-treat analysis could be performed. For binary outcomes, we determined the number of participants experiencing the outcome of interest in each group. For continuous outcomes, we used the mean change from baseline at final assessment, together with the number of participants and standard deviation for each group.
Assessment of risk of bias in included studies

Two review authors (PP and IR) evaluated the risk of bias of the included studies with respect to six domains: sequence generation, allocation concealment, blinding, incomplete outcome data, selective outcome reporting, and other sources of bias. The risk of bias in each domain was rated as high risk, low risk, and unclear. Any disagreement between raters was resolved by consensus.

Measures of treatment effect

For dichotomous data, we calculated the risk ratio (RR) and 95% CI. We calculated the mean difference (MD) and 95% CI for continuous outcomes that were measured on the same scale, otherwise we planned to calculate the standardised mean difference.

Dealing with missing data

We attempted to contact study authors to obtain any missing information.

Assessment of heterogeneity

We planned to examine the participants, interventions, and outcomes of the trials for evidence of clinical heterogeneity. Statistical heterogeneity was planned to be examined with the $I^2$ statistic and Chi$^2$ test. The $I^2$ statistic describes the percentage of total variation across studies that is due to heterogeneity rather than chance. A value of 0% indicates no observed heterogeneity; larger values show increasing heterogeneity. Substantial heterogeneity is considered to exist when $I^2$ is more than 50%. For the Chi$^2$ test, a P value of less than 0.10 was considered as indicating the presence of statistically significant heterogeneity. We planned that if there was any evidence of clinical or statistical heterogeneity, we would not conduct a meta-analysis and would report findings in a narrative form.

Assessment of reporting biases

We planned to assess reporting bias using a funnel plot.

Data synthesis

We planned to conduct a meta-analysis if the included trials were clinically homogeneous and there was no evidence of statistical heterogeneity. For dichotomous outcomes, we planned to use the Mantel-Haenszel method.

Subgroup analysis and investigation of heterogeneity

If significant heterogeneity was present, and the number of studies was sufficient, we planned to investigate heterogeneity using the following subgroups.

1. Severity of acute traumatic brain injury (mild, moderate, or severe).
2. Type of traumatic brain injury lesion (focal or diffuse).
3. Type of intervention (i.e. kind of haemostatic drug used).

Sensitivity analysis

We planned to perform a sensitivity analysis to investigate the effect of the methodological quality of the included studies on the results.

RESULTS

Description of studies

See: Characteristics of included studies; Characteristics of excluded studies; Characteristics of studies awaiting classification; Characteristics of ongoing studies.

Results of the search

The search of the databases identified a total of 659 records. These were screened by two authors (PP and IR) and the full text of 12 potentially eligible reports were obtained for closer examination. Of these, only two studies met the inclusion criteria. A further study was identified by searching the reference lists of selected seminal papers.

Included studies

Two trials were included in this systematic review. Both evaluated the effects of recombinant factor VIIa (rFVIIa). The earlier of these trials (Kluger 2007) was a post-hoc analysis of traumatic brain injury (TBI) patients from a randomised controlled trial of rFVIIa in blunt trauma patients (Boffard 2005). The later paper evaluated the effects of rFVIIa in TBI patients with evidence of intracerebral bleeding of at least 2 ml on a baseline computed tomography (CT) scan obtained within six hours of the injury (Narayan 2008). More details about the studies are reported in the ‘Characteristics of included studies’ table.

Excluded studies

We identified a trial that evaluated the effects of aprotinin in patients with severe TBI (Auer 1979). It was reported as a randomised controlled trial; however after randomly allocating the first 20 patients, five patients were added to the aprotinin group. It was not possible to separate the outcome data for the 20 randomised and the five non-randomised patients. Therefore, this study provided no usable outcome data and was excluded.
Pending study results
Another trial that could contribute useful data to this systematic review was a phase 3 randomised controlled trial that evaluated the effect of rFVIIa in trauma patients. This trial planned to recruit 1502 patients but it was stopped by its sponsor after 550 patients because of futility (Novoseven Study). Although we contacted the sponsor of this trial, as of July 2009 we were not able to obtain any data.

Ongoing studies
There are three ongoing trials that could contribute to this systematic review. The CRASH-2 trial (CRASH-2 Trial) is an international study evaluating the effects of TXA in patients with trauma and significant bleeding; a subgroup analysis of TBI patients is planned. CRASH-2 aims to recruit 20,000 patients and will be finished by December 2009. An explanatory study, CRASH-2 IBS (Intracranial Bleeding Study) is also being conducted among a sample of 300 CRASH-2 participants. In patients recruited to CRASH-2 IBS, a second CT scan is obtained within 24-48 hours after randomisation to evaluate changes in the volume of intracranial bleeding. Another trial is being conducted in Thailand to evaluate the effectiveness and safety of TXA for adult patients with moderate to severe TBI. It was to recruit 240 patients and should have been finished by May 2009 (Tranexamic acid in TBI).

Risk of bias in included studies
The review authors’ assessment of the risk of bias for each included study can be found in Figure 1 and Figure 2.

Figure 1. Methodological quality summary: review authors’ judgements about each methodological quality item for each included study.
Allocation
Method of allocation concealment was not reported in either of the included studies.

Blinding
Although both studies were reported to be ‘double blind’ they did not describe the method of blinding.

Incomplete outcome data
Both studies reported the pre-specified outcomes for all included patients. However, in the trial by Narayan and collaborators only mortality at 15 days was reported. They also reported in-hospital mortality after 15 days but it was not clear if this information was collected for all the patients.

Selective reporting
A protocol was not available for either of the included studies, so it was not possible to assess the presence of reporting bias.

Effects of interventions
We did not attempt to combine the results of the two included trials as we judged that they included two different populations. One study evaluated the effect of rFVIIa in trauma patients with extracranial bleeding who also had a TBI (Kluger 2007), and the other study only included patients with mild and moderate TBI and evidence of traumatic intracranial bleeding in the CT scan (Narayan 2008).

Primary outcomes
Mortality
Both studies reported on mortality. Kluger 2007 reported a RR for mortality at 30 days of 0.64 (95% CI 0.25 to 1.63) for patients receiving rFVIIa in comparison to those receiving placebo. Narayan 2008 reported a RR for mortality at the last follow-up time of 1.08 (95% CI 0.44 to 2.68) for patients receiving rFVIIa in comparison to those receiving placebo.

Disability
Kluger 2007 did not report the effect of rFVIIa on disability. Narayan 2008 evaluated the effect on disability using the GOS and the Barthex Index (BI).

Thrombotic complications
Both studies reported the effect of rFVIIa on thrombotic complications. Kluger 2007 followed the ‘local diagnostic procedures’ in the case of clinical symptoms of thromboembolic events. They reported two serious adverse thromboembolic events in the placebo arm.
and none in the rFVIIa arm (RR 0.16, 95% CI 0.01 to 2.99 for rFVIIa in comparison to placebo). Narayan 2008 conducted a more intense follow up of patients to detect thromboembolic complications. An ultrasound screening of the lower extremities (USLE) was mandated by protocol at 72±8 hours to detect the presence of DVT. A 12-lead electrocardiogram (ECG) and a centralised laboratory measurement of troponin I were mandated at baseline and 24 hours after trial drug administration. The authors reported that eight patients (13%) from the rFVIIa arm presented with a thromboembolic complication, while only two patients (6%) presented with such a complication in the placebo arm. The estimated RR for thrombotic complications in this study was 2.36 (95% CI 0.53 to 10.51).

Secondary outcomes
The secondary outcomes were only reported by Narayan 2008.

Intracranial bleeding volume
Narayan 2008 analysed the effect of rFVIIa on intracranial bleeding volume in different ways. For each arm, the investigators reported the: 1) mean volume at baseline, 24, and 72 hours; 2) mean volume change (defined as volume increase, no change, or decrease) at 24 and 72 hours; and 3) volume increase at 24 and 72 hours, only considering patients in whom an increase was reported. We reported the mean volume change at 72 hours as we considered this to be both the most relevant outcome and the most powerful analysis. The mean difference in volume change at 72 hours was -3.10 (95% CI -10.47 to 4.27) for patients receiving rFVIIa in comparison to patients receiving placebo. For the other secondary outcomes there were too few events to obtain effect estimate measures.

Brain ischaemic lesions
Narayan 2008 reported one cerebral infarction in the placebo arm and no events in the rFVIIa arm.

Need for neurosurgical operation or reoperation
Narayan 2008 reported the need for emergency intracranial bleeding evacuation for three patients in the placebo group and for one in the rFVIIa group. Two of the three placebo-treated patients who underwent the emergency evacuation needed a reoperation, while a reoperation was not conducted for the rFVIIa-treated patients who underwent the emergency evacuation.

Renal failure
Neither of the studies reported on renal failure.

DISCUSSION

Summary of main results
There is no reliable evidence that haemostatic drugs are effective in reducing mortality or disability in patients with TBI. Only two studies evaluating the effects of rFVIIa were found. One of them was a post-hoc analysis of a trial including 30 bleeding trauma patients with a concomitant moderate or mild TBI. This result should be considered with caution as it was a post-hoc analysis of a subgroup of patients (with TBI) within a larger trial of trauma patients. Posteriori subgroup analyses are likely to be misleading as they can be the result of data dredging and chance. The other study included 97 TBI patients with evidence of intracerebral bleeding in the initial CT scan.

Both studies were too small to confirm or refute a clinically plausible effect in the TBI population. We did not find a single randomised controlled trial of an antifibrinolytic drug for TBI patients. The pending results of the Novoseven study and the results of the ongoing studies with tranexamic acid (TXA) will provide useful information about the effects of haemostatic drugs in TBI patients.

Quality of the evidence
Neither of the trial reports provided enough data to assess the risk of bias for sequence generation, allocation concealment, blinding, or selective reporting.

Potential biases in the review process
Although our search was comprehensive and we used validated search strategies, the possibility of publication bias cannot be ruled out. Because few studies were included in this review we were not able to conduct formal analysis of publication bias (a funnel plot). Full protocols of the included studies were not available so we could not assess the presence of selective reporting bias, however for our primary outcome (mortality) this type of bias is very unlikely. Finally, one of the included trials was a post-hoc subgroup analysis and its result should be considered with caution.

Agreements and disagreements with other studies or reviews
This is the first review to evaluate the effects of haemostatic drugs in TBI patients. However, other reviews related to this question have been published. Stanworth and collaborators conducted a systematic review on rFVIIa for the prevention and treatment of bleeding in patients without haemophilia (Stanworth 2007). This review included the randomised controlled trial in trauma patients from which the post-hoc analysis reported in our systematic review was conducted (Boffard 2005). However, that review did not analyse the effect of rFVIIa in TBI patients. Another Cochrane review evaluated the effects of antifibrinolytic agents in trauma patients (Coats 2004). That review included two studies, one of them (Auer 1979) is among the excluded studies for our review. The trial involved TBI patients and the intervention under study was aprotinin, but the report provided no useable...
outcome data. The other study reported in the review by Coats and collaborators did not include TBI patients. A recent review of the clinical use of rFVIIa evaluated the effects of rFVIIa in different conditions usually treated in the emergency department (Fishman 2008). Among the outcomes, the effect on trauma patients was reported although TBI patients were not specifically included. The only included randomised controlled trial involving trauma patients was by Boffard 2005, which is included in this systematic review.

**Authors’ Conclusions**

**Implications for practice**

There is no reliable evidence to recommend the use of haemostatic drugs for TBI patients.

**Implications for research**

New randomised clinical trials assessing the effects of haemostatic drugs in TBI patients should be conducted. These trials should be large enough to detect clinically plausible effects.

Kluger 2007

Methods  Randomised clinical trial.

Participants  30 adult patients (between 16 and 65 years old) with severe blunt trauma and moderate or mild traumatic brain injury (based on CT scan results) Exclusion criteria were: cardiac arrest pre-hospital or in the emergency or operating room, prior to trial drug administration; gunshot wound to the head; base deficit of greater than 15 mEq/l or severe acidosis with pH of less than 7.00; transfusion of 8 or more units of RBCs prior to arrival at the trauma center; injury sustained greater than or equal to 12 hours before randomisation; and severe TBI, defined as a Glasgow Coma Scale (GCS) score of less than or equal to 8, unless in the presence of a normal head CT scan.

Interventions  Eligible patients were randomly assigned to treatment groups within a 4-hour period. Treatment arms were either three intravenous injections of rFVIIa (200, 100, and 100 µg/kg) or three placebo injections. The first dose of study drug was administered immediately after transfusion of the eighth unit of RBCs. The second and third doses followed 1 and 3 hours after the first dose, respectively.

Outcomes  Mortality was categorised as: early (<48 hours) or late (between 48 hours and 30 days)

Notes  This study was a post hoc analysis of patients with traumatic brain injury enrolled into a randomised, placebo-controlled study of patients with severe blunt trauma.

**Methods**
Randomised clinical trial.

**Participants**
97 adult patients (>18 years old) with traumatic brain injury, a Glasgow Coma Scale (GCS) score between 4 and 14, and evidence of traumatic intracerebral bleeding with a total volume of at least 2 ml on the baseline CT scan obtained within 6 hours of the injury.
Exclusion criteria were: the presence of penetrating head or spinal cord injury; life expectancy of less than 24 hours after hospital admission; any planned surgical evacuation of intracerebral haematoma within 24 hours after dosing; isolated subarachnoid haemorrhage, intraventricular haemorrhage, epidural or subdural haematomas or sICH; significant cardiovascular disease or dysfunction; haemodynamic instability; known history of hypercoagulability or thromboembolism; current vitamin K antagonist use; and pregnancy.

**Interventions**
Five doses of rFVIIa (40, 80, 120, 160, and 200 µg/kg) were compared with placebo in escalating dose tiers. The first dose tier (40 µg/kg) was assigned in a 1:1 ratio to the treatment or placebo group. Subsequent dose tiers were assigned in a 2:1 ratio.

**Outcomes**
The primary objective of this study was to evaluate safety of the intervention. All adverse events, defined as deep vein thrombosis (DVT), pulmonary embolism (PE), myocardial infarction, cerebral infarction, disseminated intravascular coagulation or coagulopathy were reported until day 15. Early mortality was defined as within 15 days of recruitment, and late mortality as any death after 15 days of recruitment. The effectiveness assessment focused on changes in haematoma volumes on CT scans between baseline, 24 hours, and 72 hours after the intervention.

**Notes**

**Risk of bias**

DIFFERENCES BETWEEN PROTOCOL AND REVIEW

We removed desmopressin, oestrogens, and activated factor IX from the interventions, and we focused on the most commonly used haemostatic drugs (antifibrinolytics, and rFVIIa).
