Abstract

Background: Dengue is the most prevalent mosquito-borne virus, and potentially fatal dengue hemorrhagic fever (DHF) occurs mainly in secondary infections. It recently was hypothesized that, due to the presence of cross-immunity, the relationship between the incidence of DHF and transmission intensity may be negative at areas of intense transmission. We tested this hypothesis empirically, using vector abundance as a surrogate of transmission intensity.

Methodology/Principal Findings: House Index (HI), which is defined as the percentage of households infested with vector larvae/pupae, was obtained from surveys conducted on one million houses in Thailand, between 2002 and 2004. First, the utility of HI as a surrogate of transmission intensity was confirmed because HI was correlated negatively with mean age of DHF in the population. Next, the relationship between DHF incidence and HI was investigated. DHF incidence increased only up to an HI of about 30, but declined thereafter. Reduction of HI from the currently maximal level to 30 would increase the incidence by more than 40%. Simulations, which implemented a recently proposed model for cross-immunity, generated results that resembled actual epidemiological data. It was predicted that cross-immunity generates a wide variation in incidence, thereby obscuring the relationship between incidence and transmission intensity. The relationship would become obvious only if data collected over a long duration (e.g., >10 years) was averaged.

Conclusion: The negative relationship between DHF incidence and dengue transmission intensity implies that in regions of intense transmission, insufficient reduction of vector abundance may increase long-term DHF incidence. Further studies of a duration much longer than the present study, are warranted.

Introduction

Dengue is the most prevalent vector-borne viral disease, the distribution of which has been expanding continually [1]. Dengue virus is transmitted by Aedes mosquitoes [2–4], which breed predominantly in water-holding containers within human habitats. Infections with dengue virus may manifest as dengue fever (DF), or the potentially more fatal dengue hemorrhagic fever (DHF). There are four serotypes of dengue virus, among which transient cross-protection exists [5]. Dengue virus is unique in that viral amplification in a primate host is enhanced dramatically in the presence of pre-existing immunity to a heterogeneous dengue serotype(s). This phenomenon, called antibody-dependent enhancement (ADE), had been reported initially in other arthropod-borne virus infections [6,7]. In terms of dengue, ADE was demonstrated both by in vivo [8] and animal experiments [9]. Subsequently, pre-existing hetero-serotypic antibodies were shown to be associated with elevated risk for development of DHF [10]. Although the periodicity of highly oscillatory DHF outbreaks has been under intensive study [11,12], determinants of the absolute magnitude of DHF incidence remain poorly understood. It would be understandable if the incidence of DF or DHF were affected positively by transmission intensity (measured either as force of infection or basic reproductive number). However, this intuitive thinking may be too naive in terms of dengue illness. As an example, increases in DF observed in Singapore were thought to be due to insufficient vector reduction [13,14]. This paradox may be explained as follows, at least to some extent, by the age-dependent manifestation of DF [15,16]. Under more intense transmission, infections occur at earlier ages [17]. Primary infections of younger children often result in no symptoms or mild illness [16,18]. As a result, many infections do not manifest as clinical DF under high
transmission intensity, and consequently, the incidence of DF decreases. This state of low incidence of clinical illness under intense transmission is known as “endemic stability” [15].

In contrast to DF, children seemed to be more prone to manifest DHF than are adults [19–21]. However, these studies, which did not fully consider the immunological status of the hosts, cannot be compared easily. This lack of reliable information about age-dependency in the manifestation of DHF has made it difficult to predict whether endemic stability occurs for DHF. On the other hand, a mathematical model recently predicted that, due to the presence of transient cross-serotype immunity, the incidence of DHF and transmission intensity will be correlated negatively at high transmission intensities [22]. This model hypothesized that a cross-protected individual will be seroconverted to an infecting viral serotype, while he/she is protected from manifesting severe illness. Under this assumption, which is consistent with results from experiments on monkeys [23], the individual would acquire immunity to nearly all serotypes while being cross-protected from clinical illness, at very intense transmission. As a result, the incidence of DHF could be correlated negatively to transmission intensity at areas of intense transmission, while the correlation is positive only at low levels of transmission. In the present study, such a complex correlation structure mixed with positive and negative correlations will be called “non-monotonic”, hereafter. To the contrary, correlation structure, which is simply either positive or negative, is referred to as “monotonic”.

The present study aims to provide an empirical example of this non-monotonic relationship between the incidence of DHF and transmission intensity, with transmission intensity represented by vector abundance. Vector abundance is one of the major determinants for transmission intensity of a vector-borne disease [24]. Accordingly, the WHO recommends that vector abundance be quantified in regions highly infested with Aedes through breeding site surveys and/or adult mosquito collections [25]. In developing countries, breeding site survey is preferred over mosquito collection, since the former is less labor-intensive. These surveys measure the number of houses or water containers infested by Aedes larvae/pupae through standard larval indices, such as House index (HI) and Breteau index (BI). HI is defined as the percentage of all surveyed houses in which Aedes larvae or pupae are present, while BI represents the number of infested containers in 100 houses. BI was shown to be relatively sensitive in predicting transmission [26]. Since HI and BI are strongly positively correlated [26], HI also may reflect transmission intensity to some extent. Although the absolute number of pupae is thought to reflect transmission intensity more directly than do larval indices [27–29], Southeast Asian households often possess many large water containers [30], that are irregularly shaped and partially sealed, making it difficult to obtain precise estimates of the absolute number of pupae. For this reason, absolute pupal counts have not been used in large-scale surveys in Thailand.

Here, we describe the empirical relationship between DHF incidence and transmission intensity, as represented by HI. The age-specific structure of this relationship also was characterized to support findings obtained for the entire population. The epidemiological characteristics of DHF were compared with predictions made by simulation of an individual-based model based upon the above mentioned mathematical modelling study. Our findings have major implications for future epidemiological surveys and dengue control programs.

Methods

Aedes survey

In Thailand, the highest incidence of DHF occurs between June and August. Hence, entomological surveys mainly are conducted in the pre-epidemic season (e.g., April), with the assumption that vector abundance in this season will serve as an indicator of disease incidence later in the year. Between 2002 and 2004, a large-scale national Aedes survey was conducted in all 914 districts of Thailand. The survey was intended partly for community education and was implemented by investigators dispatched from 302 vector control units and community volunteers, under the supervision of the five regional vector-borne disease control offices. The administrative central village or municipality of each sub-district was surveyed because of their accessibility. A total of 40 houses were visited in each village/municipality. Prior appointments with the residents were not made, so that the residents did not clean their houses in advance. This design, taken with incomplete house registry in rural areas, made genuine randomization impossible. Surveys were conducted in April of each year, with 9,483 villages surveyed in 2002, 9,763 in 2003, and 7,482 in 2004. The HI values were averaged for each district for comparison with district-level DHF data. The average population of a district in Thailand is 67,500.
Statistical methods

Subsequent statistical analyses were performed using R 2.6.2 and Stata 9.2. We used non-parametric statistical methods, Spearman’s rank correlation analysis and the generalized additive model (GAM), so that analyses did not have to assume any fixed distribution a priori. Akaike’s Information Criteria (AIC) inversely represented the goodness of fit, or predictability, for a regression model obtained from GAM [31]. Deviance around the prediction also was presented, although this measurement is not adjusted for degree of freedom (df) used in a regression model.

Analysis of relationship between DHF mean age and HI

To ensure that HI could be used as a reliable surrogate of transmission intensity, we compared the mean age of DHF cases to HI using rank correlation analysis. A high mean age of DHF cases was used as an indicator of low transmission intensity, because the mean age of infected individuals generally is negatively correlated with the transmission intensity of an acute infectious disease [17]. Since each district was surveyed three times (2002, 2003, and 2004), the possible bias from this repeated measurement was adjusted by simply aggregating records from three years for each district. Among the all 914 districts, this analysis incorporated 909 districts that reported at least one case of DHF between 2002 and 2004.

Analysis of the relationship between DHF incidence and HI

We examined the quantitative relationship between incidence of DHF and HI using GAM. Logarithm was used as the link function. First, we tested this relationship by incorporating only HI as the independent variable (univariate analysis). Then, we adjusted for possible confounding by socioeconomic and climatic variables. Socioeconomic factors may affect reported incidence in diverse fashions. For example, incidence may be biased by (a) the prevalence of health offices, which are responsible for DHF case reporting in each district. Abundance of breeding places is affected by local water storage practices (reviewed by [32]). Our analysis incorporated the following socioeconomic factors that were reported to be associated with dengue transmission intensity [33]: (b) per capita number of public large water wells, (c) that of public small wells, (d) that of private small wells, (e) annual birth rate per 1,000 individuals, (f) proportion of households owning land, and (g) proportion of villages in which high schools are present. These seven socioeconomic variables (a–f), censused every other year, were obtained from the Information Processing Centre of Thammasat University, Bangkok, and were interpolated linearly to the intervening years. On the other hand, dengue transmission intensity is influenced by climatic factors as well. Temperature affects critically the rate of viral amplification in mosquitoes [34]. In addition, extremely high or low temperatures are rate-determining factors for the growth and survival of mosquitoes [35]. Atmospheric vapor pressure is known to affect dengue transmission [36]. Aridity, which is likely to reflect the scarcity of underground water, may be associated with increased use of household water containers. To adjust for these possible confounders, the following climatic variables were obtained from the University Cooperation for Atmospheric Research [37]: (a) temperature averaged between January and February, the coolest months in Thailand (“winter temperature”, T1), (b) temperature averaged between April and May, the hottest months (“summer temperature”, T2), (c) average vapor pressure (AVP, hPa), and (d) average pan evapo-transpiration (APET, mm/day). These climatic variables were obtained from 89 weather stations in Thailand and its adjacent countries, averaged for each year, and interpolated to the geographic centroid of each district by using Inverse Distance Weighting method. We confirmed that multiple interpolation methods generated comparative results, perhaps because these weather stations constituted a sufficiently exhaustive dataset [38].

Collectively, these socioeconomic/climatic variables were averaged for the period for which the dependent variable, incidence, was averaged. We enrolled districts from which socioeconomic and climatic variables have been available from 1994 to 2004. Consequently, 785 districts were enrolled. This dataset (incidence linked with covariates) is available on request from the corresponding author. Multivariate analyses were conducted using the following procedure. First, HI and all socioeconomic/climatic factors were incorporated as independent variables, with df of each variable set to 2. Next, independent variables that remained significant (P<0.05) in a stepwise elimination procedure were selected, generating the “smallest regression model for df= 2”. Finally, df of each of the remaining six variables was replaced with df = 3, generating 2^6 combinations of df. Among these, the combination that exhibited the smallest AIC was adopted as the “final regression model”.

Age-stratified analysis of DHF incidence and HI

The relationship between DHF incidence and HI was examined within different age classes for which original age categories were aggregated into the following three age classes: 0–4, 5–24, and ≥25 years. GAM was applied similarly to these age-class specific incidences.

Simulation

We employed computer simulations to see whether (and to what extent) the observed epidemiological pattern could be explained based upon a theoretical framework. The assumption of the above
The mentioned mathematical model was expressed equivalently by an individual-based model (see Protocol S1, Section I). This model is summarized as follows. The cross-protective period was assumed to be of a fixed duration ("C" years). Inoculation by a virus, which occurred during this cross-protective period, does not develop into DHF, but induces seroconversion. As the cross-protective period expires, the individual is predisposed to the risk of manifesting DHF in a subsequent inoculation by a secondary (or later) serotype. An individual could manifest DHF after secondary, tertiary or quaternary infections.

In addition, this individual-based model can incorporate the age-dependency in the probability to manifest DHF (categorical parameter "A", defined in Figure S1B in Protocol S1). Transmission intensity is represented by basic reproductive number (R0) of dengue virus. The present study parameterized simulations with the following three scenarios. (I) Cross-immunity scenario: the duration of cross-serotype protection ("C") was set to two years, while the probability to manifest DHF was assumed to be independent of age ("A" = 0). We selected this duration of cross-immunity based upon the results of sensitivity analysis (see Protocol S1). (II) Age-dependency scenario: the probability to manifest DHF in secondary or later infections was assumed to increase in accordance with the age of the individual ("A" = 2), while no cross-immunity was assumed ("C" = 0). (III) Control scenario: no cross-immunity or age-dependency was assumed ("C" = 0, "A" = 0). R0 was selected by extrapolating the mean age of DHF obtained between 2002 and 2004 from each of the 785 districts, through the relationship between R0 and mean age of DHF (Figure S6 in Protocol S1). This set of R0 values was used as the input for all three scenarios. Each simulation was run for 150 years.

Comparison of predictability between simulations and actual incidence

At different durations for averaging [W], the goodness of fit was compared between the statistical models that explained the incidence in simulations versus those that explained the actual incidence. Incidences of DHF generated from simulations were averaged from the last [W] years ([W] = 3, 4 … 40) (for example, 148th, 149th and 150th years were averaged for [W] = 3). Subsequently, the averaged incidence was regressed against R0 using GAM.

On the other hand, actual incidences were averaged for the recent [W] years ([W] = 3, 4 … 11) (for example, [W] = 3 corresponds to 2002–2004; [W] = 11 corresponds to 1994–2004). Then, the averaged actual incidence was regressed against HI obtained from the 2002–2004 survey, and socioeconomic/climatic variables averaged for the recent [W] years.

Results

Relationship between mean age of DHF and HI

The national-level mean age of DHF cases was 16 years during 2002 to 2004. The mean HI recorded each April during 2002 to 2004 was 23. As shown in Figure 1, the mean age was negatively correlated with HI at the district level (Spearman’s R = −0.35, P<0.0001, N = 909).

doi:10.1371/journal.pntd.0000263.t001
During 2002 to 2004, the annual DHF incidence was 83 per 100,000 individuals. HI showed a statistically significant contribution to the log incidence of DHF, both in univariate and multivariate regression models (Table 1). Univariate analysis of GAM revealed that the correlation between HI and incidence was positive below about HI = 30, while the correlation was negative above this HI value (Figure 2B; Figure 3). As HI decreases from 70 to 30, for example, the log incidence would increase by 0.35 (Figure 3), which is equivalent to an increase of 40% in incidence, since exp (0.35) = 1.4.

In multivariate analysis, the following six variables remained in the final regression model (Table 1; Figure 4): HI, winter temperature, summer temperature, APET, public large wells, and birth rate. The best predictability (or lowest AIC) was achieved by the final regression model which assigned $df = 3$ only to public large wells, and $df = 2$ to other covariates. Multivariate analysis estimated that, as HI decreases from 70 to 30, log incidence would increase by 0.6 (Figure 4A), which corresponds to an increase of 80%.

Although incorporation of socioeconomic/variables improved the goodness of fit, this multivariate predictive model still failed to
ship in those with age-dependency (Figure 7E), and a slightly
simulations with cross-immunity (Figure 7A), a negative relation-
result, GAM detected a non-monotonic relationship in the
incidences generated by simulations and R0 (Figure 7). As a
other simulations, at any window lengths.
relationship (compare with Figure 2B). As the window for
incidence and HI was detected within the intermediate age class
(Figure 2E). A non-monotonic relationship between DHF
incidence and HI were negatively correlated in the oldest age class
(Figure 2C); whereas, DHF
incidence of DHF and HI was conducted, as shown in Table 2.
Univariate analysis revealed that incidence and HI were positively
related in the youngest age class (Figure 2C); whereas, DHF
incidence and HI were negatively correlated in the oldest age class
(Figure 2E). A non-monotonic relationship between DHF
incidence and HI was detected within the intermediate age class
(Figure 2D). When the socioeconomic/climatic variables were
incorporated, the statistical significance of positive correlation
among the youngest age class diminished (Table 2).

Simulation
As shown in Figure 6, averaging only the last three years of each
simulation resulted in a negligibly detectable relationship between
DHF incidence and R0, which greatly resembled the empirical
relationship (compare with Figure 2B). As the window for
averaging increased, the relationship generally became more
apparent. The incidences generated by simulations with cross-
immunity were much more dispersed than those generated by
other simulations, at any window lengths.

GAM was applied to examine the relationship between incidences generated by simulations and R0 (Figure 7). As a
result, GAM detected a non-monotonic relationship in the
simulations with cross-immunity (Figure 7A), a negative relation-
ship in those with age-dependency (Figure 7E), and a slightly
positive relationship in the control simulations (Figure 7I). Age-
stratification of the simulation results generated a similar trend in
the empirical data, regardless of the presence of cross-immunity or
age-dependency (Figure 7B–D, F–H, J–L). That is, a positive
correlation was observed between DHF incidence and transmis-
sion intensity in the younger population, and a negative
correlation was present in the older population.

Comparison of predictability
The goodness of fit in predicting incidence by R0 showed
remarkable differences between simulation with cross-immunity
and those without cross-immunity (Figure 8). The predictability
was much worse in simulation with cross-immunity than in other
simulations. In addition, the response to the window length was
more complex in the presence of cross-immunity than in other
simulations. That is, in simulations without cross-immunity,
the predictabilities improved continuously as W increased. In contrast,
the predictability in the presence of cross-immunity deteriorated as
the window for averaging increased from W = 3 to W = 4, then
improved up to W = 6. With a small setback at W = 7, it improved
again thereafter. Such a complex response of predictability to W
was reproduced at diverse durations of cross-immunity (Figure 9),
which were sufficiently long to generate dominant supra-annual
periodicities (see Section II and Figure S7 in Protocol S1).

The goodness of fit in predicting actual incidence, either by HI
only or by HI and covariates, showed a similarly complex response
to W (Table 3). The predictability attained solely by HI was much
inferior to that attained in any simulations (Figure 8). However,
the predictability using the multivariate regression model was as
good as that in simulations with cross-immunity, up to W = 8.

Discussion
Our analysis demonstrates that HI is a reliable indicator of
transmission intensity, at least at the district level. The usefulness
of HI is evident by its highly significant, inverse relationship to
mean age, otherwise equivalent to a positive correlation between
HI and transmission intensity. Our findings are consistent with
observations from Singapore, where an increase in the mean age
of patients with dengue infection was preceded by a substantial
reduction in HI [13,14].

Analysis of DHF incidence among the entire Thai population
revealed that incidence rose up to HI of about 30 and gradually
declined thereafter. This non-monotonic relationship appears to
be consistent with a state of endemic stability. However, the age-
dependency in the probability to manifest DHF may not simply
satisfy the condition for endemic stability, because DHF occurs
more frequently in children than in adults. On the other hand,
cross-immunity explains not only this non-monotonic relationship
(Figure S2 in Protocol S1), but also the wide variation in incidence
of DHF, as well as its complex response to the duration of window
for averaging (Figure S8 in Protocol S1). Of note, the regression
model comprised of HI and socioeconomic/climatic variables
predicted actual incidence to the same goodness of fit, with which
φ0 predicted incidence from simulations with cross-immunity
(Figure 8). This finding may support the validity of the multivariate
regression model, and that of our assumption for cross-immunity,
simultaneously.

Stratification of data according to age revealed a positive
association between DHF incidence and HI among the youngest
population. In contrast, a negative association was observed in the
oldest population. These contrasting correlations may be
explained as follows. Under low transmission intensity, the
majority of individuals in the youngest age class do not possess

Figure 3. Non-linear responses of the log incidence of DHF to House Index, revealed by univariate analysis of generalized
additive model (GAM). The smoothing function obtained from GAM
analysis, which regressed the log of DHF incidence reported between
2002 and 2004 against House Index, is presented as the solid line.

reproduce the very wide variation in the observed incidence
(compare Figure 2B vs Figure 5).

Age-specific relationship between DHF incidence and HI
Further analysis of the age-specific associations between
incidence of DHF and HI was conducted, as shown in Table 2.
Univariate analysis revealed that incidence and HI were positively
related in the youngest age class (Figure 2C); whereas, DHF
incidence and HI were negatively correlated in the oldest age class
(Figure 2E). A non-monotonic relationship between DHF
incidence and HI was detected within the intermediate age class
(Figure 2D). When the socioeconomic/climatic variables were
incorporated, the statistical significance of positive correlation
among the youngest age class diminished (Table 2).

www.plosntds.org 6 July 2008 | Volume 2 | Issue 7 | e263
antibodies against any serotype and are relatively resistant to DHF. As the transmission intensity increases, a larger number of individuals in this age class possess antibodies to only one serotype, making them predisposed to DHF. Therefore, the correlation between DHF incidence and transmission intensity becomes positive in the youngest age class, as observed here. In contrast, when transmission intensity is low, many in the oldest age class possess antibodies against only one serotype and are predisposed to DHF. As transmission intensity increases, more members of this age class possess antibodies against almost all serotypes, conferring
resistance to DHF. Importantly, these age-stratified relationships could be reproduced by simulations of any scenarios examined. Therefore, this analysis did not differentiate whether cross-immunity or age-dependency determined the epidemiological characteristics of DHF.

The negative response of incidence to transmission intensity at areas of intense transmission has important public health implications, regardless of its underlying mechanism. The incidence of DHF is affected by the dominant virus serotype, which shifts from period to period [39,40]. In addition, HI measured in one country cannot be compared with HI in another country. Since our analysis was based on a single three-year period in one country, the stability of our estimated HI value at the national scale in developing countries. Instead, reduction of the vector population may become stagnant as the vector abundance decreases. Furthermore, even substantial vector reduction (for example, from HI = 60 to 10) would not necessarily decrease the final incidence (extrapolate the HI values to incidence in Figure 3), but would result most likely in a greater number of DHF cases accumulated over the course of time. This calculation suggests that it is extremely difficult for vector control alone to achieve the ultimate goal of control program—reduction of incidence.

**Figure 7.** Age-specific relationship between DHF incidence and transmission intensity predicted by simulations. Age-stratified incidence of DHF in the last three years from each simulation were averaged. The parameters inputted to simulations were: two-year cross-immunity \((A-D)\); age-dependency which assumes a higher probability of manifesting DHF in older individuals \((E-H)\); control scenario without cross-immunity or age-dependency \((I-L)\). DHF incidence presented for the entire population \((A, E, I)\) or stratified into 0–4 years \((B, F, J)\), 5–24 years \((C, G, K)\), and ≥25 years \((D, H, L)\). Y-axis is log scale.

**Figure S4** Relationship between DHF incidence and transmission intensity generated by transmission enhancement. Transmission enhancement \((E)\) during manifesting DHF was assumed to be 1 (no enhancement), 2 or 20. No age-dependency or cross-
protection was assumed (i.e., \(A = 0\), \(C = 0\) year). Infection with four serotypes was required to confer life-long immunity (\(L = 4\) serotypes). Qualitatively similar results were obtained with \(L = 2\) or \(3\).

Figure 8. Goodness of fit in predicting the incidence of DHF obtained either from actual epidemiological data, or from simulations. The goodness of fit in the regression models for incidence of DHF is plotted over the window length ("W") with which the incidence was averaged. For actual epidemiological data, the most recent \(W\) years descending from 2004 were averaged. For simulations, the last \(W\) years in each simulation were averaged. Actual incidence was regressed against HI only (square), or against HI and socioeconomic variables (circle) (Table 3), while incidence in simulations were regressed against \(R_0\) with \(df = 2\) assigned. The goodness of fit as inversely measured by Akaike's Information Criterion (AIC) (A), and the deviance (B) were obtained from GAM models. The scenario parameters for simulations were: cross-immunity (X), age-dependency (diamond); or control scenario without cross-immunity or age-dependency (triangle).

doi:10.1371/journal.pntd.0000263.g008

Figure 9. Responses of predictability of DHF incidence to the window length for averaging, at diverse durations of cross-immunity. The predictability of DHF incidence was inversely measured by deviance and plotted to \(W\) (see the legend for Figure 8). Simulations with diverse durations of cross-immunity examined in the sensitivity analysis are compared. The results for cross-immunity (C) of 0, 0.5, 2 and 4 years are presented.

Figure S5 Temporal pattern of alternating serotypes in the presence of cross immunity and effects of a sudden drop in transmission intensity. Examples of serotype-specific incidence of DHF are presented. The last 40 years are presented.

Found at: doi:10.1371/journal.pntd.0000263.s007 (1.18 MB TIF)

Figure S6 Relationship between mean age of DHF cases and Dengue transmission intensity (\(R_0\)). Mean age of DHF cases is plotted against transmission intensity (\(R_0\)). The result for a parameter setting (\(C = 2\) years, \(L = 4\) serotypes, \(A = \) no age-dependency, \(E = 1\)) is presented. All other parameter combinations examined generated similarly negative correlations between mean age of DHF cases and \(R_0\).

Found at: doi:10.1371/journal.pntd.0000263.s008 (0.14 MB TIF)

Figure S7 Periodicity profile (periodogram) for incidence generated by simulations for Dengue Hemorrhagic Fever (DHF). Individual-based simulation for DHF (described in the accompanying manuscript) was executed for 150 years, from which monthly incidence for the last 40 years was analyzed by fast Fourier transform with Daniell smoothing (provided in R 2.6.2). Parameters for simulations are as follows: cross-immunity of 0.5 year (A–C), one year (D–F), two years (G–I), three years (J–L), and four years (M–O); age-dependency, which attributes a higher probability of manifesting DHF to the older population [defined as \(A = 2\) in the accompanying manuscript] (P–R); control (i.e., no cross-immunity, no age-dependency) (S–U). Transmission intensity inputted to simulations were \(R_0 = 3\) (A, D, G, J, M, P, S), \(R_0 = 6\) (B, E, H, K, N, Q, T), or \(R_0 = 12\) (C, F, I, L, O, R, U). We executed each parameter setting in duplicate, and confirmed that the resulting periodograms were very similar. The highest spectrum intensity was presented as 1, for each parameter setting.
Table 3. Contribution of vector abundance and socioeconomic/climatic factors in explaining log incidence of DHF averaged over diverse durations, revealed by GAM.
