OBJECTIVE — To estimate and compare associations of alanine aminotransferase (ALT) and γ-glutamyltransferase (GGT) with incident diabetes.

RESEARCH DESIGN AND METHODS — ALT and GGT were studied as determinants of diabetes in the British Women’s Heart and Health Study, a cohort of 4,286 women 60–79 years old (median follow-up 7.3 years). A systematic review and a meta-analysis of 21 prospective, population-based studies of ultrasonography, which diagnosed nonalcoholic fatty liver disease (NAFLD), ALT, and GGT as determinants of diabetes, were conducted, and associations of ALT and GGT with diabetes were compared.

RESULTS — Ultrasonography-diagnosed NAFLD was associated with more than a doubling in the risk of incident diabetes (three studies). ALT and GGT both predicted diabetes. The fully adjusted hazard ratio (HR) for diabetes per increase in one unit of logged ALT was 1.83 (95% CI 1.57–2.14; I² = 88%) and for GGT was 1.92 (1.66–2.21; I² = 55%). To directly compare ALT and GGT as determinants of diabetes, the fully adjusted risk of diabetes in the top versus bottom fourth of the ALT and GGT distributions was estimated using data from studies that included results for both markers. For ALT, the HR was 2.02 (1.59–2.58; I² = 27%), and for GGT the HR was 2.94 (1.98–3.88; I² = 20%), suggesting that GGT may be a better predictor (P = 0.05).

CONCLUSIONS — Findings are consistent with the role of liver fat in diabetes pathogenesis. GGT may be a better diabetes predictor than ALT, but additional studies with directly determined liver fat content, ALT, and GGT are needed to confirm this finding.

Diabetes Care 32:741–750, 2009

Nonalcoholic fatty liver disease (NAFLD) is characterized by accumulation of fat in the liver, with or without inflammation, fibrosis, and cirrhosis, in the absence of substantial alcohol consumption or other causes of liver disease such as viral hepatitis. In large epidemiological studies, NAFLD and liver fat content (a continuum) are commonly revealed by elevations in alanine aminotransferase (ALT), γ-glutamyltransferase (GGT), and ultrasonography.

High rates of elevated GGT levels were noted among diabetic patients over 40 years ago (1). Cross-sectional associations between abnormal GGT and dysglycemic states were also documented in the 1980s (e.g., the study by Ford et al. [2]). However, cross-sectional studies cannot determine causality because in most cases it is impossible to ascertain the temporal sequence between the events studied. The first longitudinal study to examine the association of a biomarker of NAFLD with incident diabetes was published in 1998 (3). Since then, both ALT and GGT, even within the normal range, have been reported to predict incident diabetes. However, while some studies have demonstrated a stronger association between GGT and diabetes than between ALT and diabetes (4,5), other studies have reported the opposite (6).

To our knowledge, no previous publication has systematically reviewed and meta-analyzed all prospective studies of the association between NAFLD and its markers with future diabetes risk. We are also unaware of any studies that have compared the magnitude of the relative associations between ALT and GGT with diabetes risk, despite claims for one or the other being a better marker of liver fat and thus diabetes risk. We therefore examined the separate associations of ALT and GGT with incident diabetes in a population of older British women and undertook a systematic review and meta-analysis of prospective population-based studies assessing the associations of NAFLD, ALT, or GGT with diabetes. Of note, while aspartate aminotransferase has also been assessed in some studies (e.g., in the study by André et al. [4]), it is not as sensitive or specific to liver damage as ALT or GGT (7) and is therefore not addressed here.

RESEARCH DESIGN AND METHODS

British Women’s Heart and Health Study

Full details of the selection of participants and measurements have been previously reported (8–10). A total of 4,286 women, aged 60–79 years, were randomly recruited from 23 British towns. Baseline data (self-completed questionnaire, research nurse interview, physical examination, and medical record review) were
collected between 1999 and 2001. These women have been followed up for a median of 7.3 years, to September 2007, by a detailed review of their medical records conducted every 2 years and by a self-completed questionnaire. Informed consent was obtained from the women, and the approval of both the local and multicenter ethics committees was obtained for the study.

Levels of GGT and ALT were determined in fresh serum samples using an automated analyzer (Technicon Sequential Multiple Analyzer; Technicon Instruments Corporation, Tarrytown, NY). Waist and hip circumference, lipids, fasting glucose and insulin, and blood pressure were measured using standard methods as previously described. Information on smoking, physical activity, social class, and alcohol consumption was obtained from a self-completed questionnaire and nurse interview (9).

Insulin resistance was estimated according to the homeostasis model assessment (HOMA) as the product of fasting glucose (millimoles per liter) and insulin (microunits per millilitre) divided by the constant 22.5 (11). Baseline diabetes (for those with no evidence of diabetes at the end of follow-up) was the time axis and risk was assessed using the Cox proportional hazards regression models, the participant’s age and smoking were adjusted plus HOMA, waist-to-hip ratio, triglycerides, HDL cholesterol, and systolic blood pressure.

The objective of the second meta-analysis was to directly compare the associations of ALT and GGT with diabetes. We decided a priori to limit this second analysis to results of studies that provided estimates for both ALT and GGT in the same population in order to ensure the comparability of the estimates for ALT and GGT. Furthermore, only studies for which we could obtain results in which ALT and GGT had been standardized (to account for their different distributions) were included. The most common method used to standardize ALT and GGT was to present results per fourths of the ALT and GGT distributions. Therefore, we combined the RRs in the top versus the bottom fourth of the ALT and GGT. A fixed-effects model was used, thus assuming that the true effect in all studies was the same and any difference between study results was due to chance alone, and this assumption was checked using the I² measure (13).

When possible, data were extracted separately for men and women. The effect of duration of follow-up on study results was assessed by meta-regression. Small-study effects such as publication bias were examined by using a funnel plot (16) and formally tested using the Egger test (17).

**RESULTS**

**British Women’s Heart and Health Study**

Data on diabetes at baseline were available for 3,829 women (89% of 4,286), of whom 377 had diabetes and were excluded from the analysis. Of the remaining 3,452 women, 3,041 (88% of 3,452) had complete data on all covariables (Table 1). Characteristics of included women by diabetes status at the end of follow-up are presented.

| Table 1—HRs (95% CI) of incident diabetes per SD change of natural logged ALT and GGT |
|-------------------|-------------------|-------------------|-------------------|-------------------|
|                   | Model 1           | Model 2           | Model 3           | Model 4           |
| ALT               | 1.50 (1.27–1.74)  | 1.51 (1.29–1.77)  | 1.37 (1.15–1.64)  | 1.20 (0.99–1.44)  |
| GGT               | 1.55 (1.34–1.79)  | 1.55 (1.35–1.79)  | 1.46 (1.25–1.71)  | 1.24 (1.04–1.48)  |

Model 1, adjusted for age; model 2, model 1 adjustment plus alcohol consumption; model 3, model 2 adjustments plus childhood and adult social class, physical activity, and smoking; model 4, model 3 adjustments plus HOMA, waist-to-hip ratio, triglycerides, HDL cholesterol, and systolic blood pressure.
in Table A1 (available in an online appendix at http://care.diabetesjournals.org/cgi/content/full/dc08-1870/DC1). Women with diabetes at the end of follow-up were older; had higher age-adjusted mean BMI, waist-to-hip ratio, ALT, GGT, triglycerides, glucose, and HOMA; and had lower HDL cholesterol. More of the women with incident diabetes exercised for <2 h per week, and more also had a history of smoking.

During 281,081 person-years of follow-up, 112 women were diagnosed with diabetes, yielding a rate of 5.3 per 1,000 person-years (95% CI 4.4–6.4). Both ALT and GGT were associated with incident diabetes, even when adjustment was made for alcohol consumption (Table 1) and other potential confounders. When components of the metabolic syndrome were added to the model, the associations of both ALT and GGT with incident diabetes were attenuated toward the null. The 95% CI crossed the null for ALT but not for GGT. However, the magnitude of associations of ALT with diabetes and of GGT with diabetes was comparable in all four models, as was the degree of attenuation of age-adjusted estimates.

**Systematic review and meta-analysis**

The electronic search (crossing terms for ALT, GGT, liver steatosis, and diabetes) yielded 236 potentially relevant publications, of which 20 studied prospective population-based cohorts and assessed baseline ultrasonography-diagnosed NAFLD, ALT, and/or GGT and their associations with incident diabetes.

**Ultrasound-diagnosed NAFLD**

Three studies (18–20) (summarized in Table 2) assessed ultrasound-diagnosed NAFLD as a determinant of incident diabetes. No studies that used any other diagnostic test to ascertain NAFLD in its association with incident diabetes were retrieved. All three studies were conducted in Asian populations, and in all three there was evidence that ultrasound-diagnosed NAFLD was associated with diabetes risk. When estimates from these studies were meta-analyzed (using the estimate of mild vs. no NAFLD from the study by Kim et al. [18]), the pooled RR was 2.52 (95% CI 1.07–5.96), but there was evidence of considerable heterogeneity between studies ($I^2 = 90\%$).

**ALT and GGT**

Study characteristics of the 18 prospective population-based studies of the associations of ALT and/or GGT with incident diabetes are also summarized in Table 2. Ten studies ($+6.21–28$) (including the current analysis of the British Women’s Heart and Health Study [BWHHS]) assessed both ALT and GGT as predictors of diabetes, an additional three studies looked at ALT only (29–31), and another four studies looked at the association of GGT with diabetes risk (3.32–34). Age-adjusted and fully adjusted study results examining (natural logged) ALT and GGT as determinants of incident diabetes were pooled (separately).

A change in one logged unit in ALT was associated with an HR of 3.05 (95% CI 2.59–3.59, $I^2 = 26\%$, 13 comparisons) and in GGT 2.56 (2.31–2.84, $I^2 = 32\%$, 17 comparisons) (online appendix Fig. A1). The meta-analysis of fully adjusted results for both ALT and GGT are presented in Fig. 1. The fully adjusted HR for diabetes per increase in one unit of logged ALT was 1.85 (1.57–2.18, $I^2 = 19\%$, 14 comparisons), and in one unit of logged GGT the HR was 1.92 (1.66–2.21, $I^2 = 55\%$, 18 comparisons).

No strong evidence was found for the presence of a small-studies effect for ALT or GGT. There was also no strong evidence of an association between duration of follow-up and study results (all $P >0.69$).

**Comparing associations of ALT and GGT with incident diabetes**

Seven studies (including the BWHHS) contributed to the analysis of ALT and GGT categorized in fourths as predictors of diabetes (4,5,21,22,24,25). Additional studies assessed both ALT and GGT; however, one used fifths (26,27), another used tenths (6), and a final study (28) used fourths but did not present results in full and therefore could not be included in this analysis. Age-adjusted pooled analyses of the included studies are presented in online appendix Figure A2. The RR in the top versus the bottom quartile of ALT was 4.42 (95% CI 3.61–5.42, $I^2 = 42\%$), and for GGT it was 5.87 (4.63–7.44, $I^2 = 21\%$). The fully adjusted RR for ALT was 2.02 (1.59–2.58, $I^2 = 27\%$) and for GGT 2.94 (1.98–3.88, $I^2 = 20\%$) (Fig. 2). According to a formal statistical test for heterogeneity between estimates for ALT and GGT, there was some evidence suggesting that pooled estimates for GGT were larger than those for ALT (age-adjusted results, $P = 0.08$, and fully adjusted results, $P = 0.05$).

However, repeating the analysis after excluding results for women in the DESIR (Data From the Epidemiological Study on the Insulin Resistance Syndrome) cohort (4), which was the only study that showed a potential protective effect of ALT, resulted in greater pooled estimates for GGT (HR 2.91 [95% CI 2.19–3.85]) than for ALT (2.12 [1.66–2.72]) but no strong evidence for heterogeneity between the estimates ($P = 0.10$ for both age-adjusted and fully adjusted results).

**CONCLUSIONS** — Ultrasound-diagnosed NAFLD, ALT, and GGT all predicted diabetes risk. NAFLD defined by ultrasound was associated with more than a doubling of the risk of incident diabetes. In a meta-analysis of fully adjusted results (albeit variably adjusted) of all population-based, systematically identified prospective studies, a 1 unit/l increase of natural logged ALT was associated with an 85% increase in diabetes risk and a 1 unit/l increase of natural logged GGT was associated with a 92% increase in diabetes risk.

A second meta-analysis that assessed the association of both ALT and GGT (using fourths of their distribution) with incident diabetes in the same populations was performed. Belonging to the top fourth of the GGT distribution was associated with a 194% increase in the risk of diabetes compared with risk increase associated with belonging to the bottom fourth. For ALT, the corresponding increase in the risk of diabetes was 102%, with formal evidence of heterogeneity between these two estimates (both based on fully adjusted models).

There are two possible explanations for the potentially stronger association of GGT with diabetes compared with that of ALT. First, both ALT and GGT are biomarkers of liver fat, but GGT may simply be the better marker. In light of the paucity of relevant evidence as to which liver enzyme better reflects liver fat content, this explanation cannot be ruled out. However, GGT is present on the surface of most cell types and is highly active in organs other than the liver, such as the kidney and pancreas (35). Therefore, ALT is considered a more liver-specific marker than GGT. GGT is the enzyme responsible for the extracellular catabolism of antioxidant glutathione (36) and may be linked to greater oxidative stress (37). Because oxidative stress has been implicated in insulin resistance, diabetes, and cardiovascular disease (37,38), GGT’s potentially stronger association with diabetes may reflect its associations with several...

different processes relevant to diabetes pathogenesis. This speculative suggestion requires more data.

Although a stronger association of GGT (compared with that of ALT) with diabetes is biologically plausible, our results should be interpreted with caution. The exclusion of a single observation substantially reduced the strength of evidence that the associations of ALT and GGT with incident diabetes were different. In addition, some limitations should be noted. Only 6 of the 10 studies that presented results for both ALT and GGT could be included in the meta-analyses of the risk estimates in the top fourth of the ALT and GGT distributions versus the bottom fourth (despite our best efforts to contact and obtain relevant information from authors, results in the form necessary to include the additional three studies were not forthcoming). An additional limitation is that two of the studies included in the systematic review could not be included in the meta-analysis of all studies as a result of missing information. Attempts were made to obtain additional results from study authors, but this was not always possible. Limitations of the BWHHS include the lack of oral glucose tolerance testing at baseline, the use of self-reported medical diagnoses of diabetes at follow-up, a less robust measure of insulin resistance (HOMA), and the inclusion of women only. The latter is also the study’s strength because 6 of the 18 studies do not include any women.

In conclusion, NAFLD and associated elevations in liver enzymes are associated with incident diabetes above and beyond commonly measured diabetes risk factors. Results suggest that the association of GGT with diabetes risk may be of greater magnitude than that of ALT with diabetes, but further studies are needed to confirm this. In the meantime, raised levels of both enzymes in the context of other clinical features of insulin resistance (obe-
sity, hypertriglyceridemia, raised fasting glucose, etc.) give good insight into excess hepatic fat and thus elevated diabetes risk.

Acknowledgments — We thank the U.K. Department of Health Policy Research Programme for core support to the BWHHS and the British Heart Foundation for additional funding. A.F. receives support from the University of Bristol Overseas Research Student Award Scheme, and D.L. is funded by a U.K. Department of Health career scientist award.

No potential conflicts of interest relevant to this article were reported.

We thank the following authors for their assistance with our work: Ele Ferranni, CNR (National Research Council) Institute of Clinical Physiology; Duk-Hee Lee, Kyungpook National University; Matteo Monami, U.O. Geriatria Universitaria; and Matthias Schulze, German Institute of Human Nutrition. The BWHHS is codirected by Shah Ebrahim, Debbie Lawlor, Peter Whincup, and Goya Wannamethee. We thank Carol Bedford, Alison Emerton, Nicola Frecknall, Karen Jones, Mark Taylor, Simone Watson, and Katherine Worrell, together with Rita Patel, for collecting and entering data; all of the general practitioners and their staff who have supported data collection; and the women who have participated in the study.
