Variability in interpretation of chest radiographs among Russian clinicians and implications for screening programmes: observational study

Y Balabanova, R Coker, I Fedorin, S Zakharova, S Plavinskij, N Krukov, R Atun, F Drobniewski

Abstract

Objective To determine variability in interpretation of chest radiographs among tuberculosis specialists, radiologists, and respiratory specialists.

Design Observational study.

Setting Tuberculosis and respiratory disease services, Samara region, Russian Federation.

Participants 101 clinicians involved in the diagnosis and management of pulmonary tuberculosis and respiratory diseases.

Main outcome measures Interobserver and intraobserver agreement on the interpretation of 50 digital chest radiographs, using a scale of poor to very good agreement (κ coefficient: ≤0.20 poor, 0.21-0.40 fair, 0.41-0.60 moderate, 0.61-0.80 good, and 0.81-1.00 very good).

Results Agreement on the presence or absence of an abnormality was fair only (κ=0.380, 95% confidence interval 0.376 to 0.384), moderate for localisation of the abnormality (0.448, 0.444 to 0.452), and fair for a diagnosis of tuberculosis (0.387, 0.382 to 0.391). The highest levels of agreement were among radiologists. Level of experience (years of work in the specialty) influenced agreement on presence of abnormalities and cavities. Levels of intraobserver agreement were fair.

Conclusions Population screening for tuberculosis in Russia may be less than optimal owing to limited agreement on interpretation of chest radiographs, and may have implications for radiological screening programmes in other countries.

Introduction

Clinical interpretation of chest radiographs is important in the control of tuberculosis. Studies have examined intraobserver and interobserver agreement in interpretation of chest radiographs, and significant disagreement between observers has been reported.

Radiological examination plays an important part in the diagnosis and monitoring of tuberculosis, particularly in countries of the former Soviet Union such as the Russian Federation. The control of tuberculosis in Russia remains a challenge and an economic burden (incidence 86.0 per 100 000 population and mortality 21.5 per 100 000 population in 2002). Case finding is based on fluorographic screening of the population, and diagnosis may be made on the basis of radiological abnormalities without bacteriological confirmation.

The monitoring of treatment, the definition of cure, and the granting of permission for patients with tuberculosis to return to work after therapy largely depend on the resolution of radiological abnormalities. In Russia the validity of interpretation of chest radiographs is essential if the benefits of screening and monitoring of treatment are to be realised. In public health terms, false positive diagnoses will result in inefficient use of resources, and false negative diagnoses may pose a threat to public health through spread of tuberculosis. Misdiagnosis of active tuberculosis as latent infection and subsequent use of single drug chemoprophylaxis may result in drug resistance.

We determined interobserver and intraobserver variability in interpretation of chest radiographs among a group of Russian clinicians from the disciplines of radiology, respiratory medicine, and tuberculosis.

Methods

Our study was carried out in Samara, a Russian city about 1000 km south east of Moscow (population 1.2 million). We invited to take part in our study all specialists in tuberculosis, respiratory physicians from the two main local general hospitals, radiologists specialising in tuberculosis, and general radiologists.

The study material consisted of 50 high resolution digital posterior-anterior chest radiographs, selected from the archives at King’s College Hospital, London, which had a diagnosis—that is, they were interpretable. Thirty seven of the radiographs showed an abnormality and 13 were reported as normal. The 37 abnormal radiographs comprised 20 (54%) reported as tuberculosis, 7 (19%) reported as lung cancer, 5 (14%) reported as pneumonia, 4 (11%) reported as sarcoid, and 1 (3%) reported as fibrosing alveolitis. Twenty patients who were described as having tuberculosis on the basis of the chest radiograph were culture positive for Mycobacterium tuberculosis. The remaining 17 people had culture negative results for tuberculosis.

To assess intraobserver agreement, we randomly repeated 10 pairs of radiographs in the set. The participants were familiar with the digital format, as both conventional film radiographs and digital radiographs are used in Russia. For general population screening, however, a small radiograph (fluorogram) is used, which has much poorer resolution than digital radiographs. We converted these series of digital images into a high resolution slide presentation (Microsoft Powerpoint), which was reviewed by each participant in a darkened room during a single viewing session, independently from the other participants. The participants were given unlimited time to familiarise themselves with the radiographs.

Table showing levels of experience is on bmj.com
themselves with images on the computer before they reviewed the radiographs. Abnormal and normal images were randomly mixed and each participant reviewed them in the same order. Each image was reviewed for two minutes, a period determined from a pilot study. This time also approximates to that spent reviewing images in population screening. No clinical information was provided, reflecting the normal situation of population screening. The participants were not allowed to review images they had already seen.

The participants recorded their interpretation of each radiograph on a structured questionnaire, using a five point scale: 1 = normal; 2 = abnormal but not clinically important; 3 = not certain, warrants further diagnostic evaluation; 4 = abnormal diagnosis uncertain, warrants further diagnostic evaluation; and 5 = abnormal—diagnosis apparent but warrants appropriate clinical management.

The questionnaire also included categorical questions requiring yes or no answers on the localisation of an abnormality and the presence of cavities. The participants were asked whether the radiographic findings were consistent with a diagnosis of tuberculosis and, if so, which form (according to the Russian classification system) and whether it was likely to be active. If observers suspected another diagnosis, they were asked to state the most likely diagnosis as free text.

Statistical analysis

We generated a receiver operating curve for three subgroups: tuberculosis specialists, general radiologists, and respiratory specialists. To decrease the subjectivity of a single expert decision (for example, the UK radiologist or specialist who reported on the original chest radiograph) and to limit bias due to differences in professional practice between UK and Russian clinicians, we took a reference standard from a majority decision of the specialist radiologists on the question of whether the findings were consistent with tuberculosis. We used this standard to compare the performance of the other participants with that of the specialist radiologists. The participants were blind to the reference standard.

To assess interobserver agreement among the participants and within the three subgroups, we used $\kappa$ statistics for multiple observers ($\kappa_m$), which is a measure of agreement beyond the level of agreement expected by chance alone. We also used $\kappa$ statistics to measure intraobserver agreement between the two reports of radiographs that had been repeated. We adopted the guidelines for interpretation of $\kappa$ coefficients from Altman: $<0.20$, poor agreement; $0.21-0.40$, fair agreement; $0.41-0.60$, moderate agreement; $0.61-0.80$ good agreement; and $0.81-1.00$ very good agreement; we also calculated $95\%$ confidence intervals. By averaging the $\kappa$ values of each lung zone, we calculated the mean interobserver and intraobserver $\kappa$ statistics for localisation of an abnormality.

We analysed the data using Stata8, SAS release 8.2, and SPSS12.

Results

Overall, 61 of 80 (76%) tuberculosis specialists agreed to participate in our study, as did 15 of 18 (83%) respiratory specialists, all 12 specialist radiologists, and all 13 general radiologists (see table on bmj.com).

Overall agreement on the presence or absence of an abnormality on chest radiographs was fair only ($\kappa = 0.380$). Interobserver agreement was highest when we compared both normal findings and abnormal but not clinically important findings with the other responses (not certain, warrants further diagnostic evaluation; abnormal diagnosis uncertain, warrants further diagnostic evaluation; and abnormal—diagnosis apparent but warrants appropriate clinical management), although even then agreement was only moderate (0.479).

Agreement on localisation of abnormalities was moderate only (0.448; range 0.351-0.547) and agreement on determining a diagnosis of tuberculosis was fair only (0.387). For each of the 50 radiographs reviewed, tuberculosis was offered as a diagnosis by at least one participant. Agreement was highest among the radiologists, but still only moderate (0.448; table 1).

When we combined normal findings with abnormal but not clinically important findings, the more experienced participants showed greater agreement on presence or absence of abnormalities (0.388, $95\%$ confidence interval 0.383 to 0.393; 0.355, 0.316 to 0.353) and detection of cavities (0.450, 0.444 to 0.456; 0.354, 0.331 to 0.376), but not when we took all five responses into account. Level of experience made little difference to agreement on presence or absence of abnormalities (0.388, 0.383 to 0.393; 0.355, 0.316 to 0.353).

Intraobserver agreement among Russian clinicians on evaluation of chest radiographs. Values are

Discussion

The interpretation of chest radiographs by Russian clinicians involved in the screening for and treatment of tuberculosis in Samara region is highly subjective and agreement was often low.

As Samara is a typical Russian city we believe that our findings may be generalisable throughout the Russian Federation. Levels of agreement were similar to other reports but these studies were not carried out in settings where mass population screening is routine practice, nor in a post-Soviet environment. Moreover, these studies included radiologists whose opinion may have been influenced by that of work colleagues.

In our study, professional experience had some influence on the ability to detect abnormalities, including cavities, which may be a prerequisite for any successful method for screening populations. In general, the effect of professional professional seniority on levels of diagnostic agreement was limited. Intraobserver agreement was not high overall, with radiologists showing most consistency in agreeing with their previous opinions on chest radiographs.

The effectiveness of the Russian model of screening (general population screening is mandatory and annual targets are set) depends highly on the validity of the tools used (radiology) and the interpretation of findings. Given the relatively low intraobserver and interobserver agreement we found in the interpretation of chest radiographs by Russian clinicians, the implications are profound. A significant number of the general population may be wrongly told that they have tuberculosis, as the probability is extremely low. This has repercussions both for the individual and for the tuberculosis programme, as considerable scarce resources (budget expenditure and professionals’ time) may be used to exclude a diagnosis of tuberculosis. Undercapacity in microbiological laboratory services (the case in much of Russia, but not in Samara) means that refuting a putative diagnosis of tuberculosis is prone to error. It seems likely that many people are potentially wrongly diagnosed as having tuberculosis. Moreover, many patients with tuberculosis may not be identified.

Our study was limited in two ways. Firstly, owing to the small number of chest radiographs selected for second review, the k values for intraobserver agreement had wide and statistically insignificant confidence intervals. Secondly, the presence and type of abnormality was based on only one plain posterior-
