ABSTRACT

*Trypanosoma cruzi* and the *Leishmania donovani* complex are parasitic protozoa that, respectively, cause Chagas disease in the Americas, and visceral leishmaniasis, predominantly in South Asia, East Africa, and Brazil.

*T. cruzi* is divided into the lineages TcI-TcVI. The relationship between infecting lineage(s) and spectrum of clinical presentations remains poorly understood. This project developed lineage-specific serology to identify an individual’s history of lineage infection. A high level of polymorphism in the surface mucin TSSA was identified, and lineage-specific synthetic peptides based on this diversity were applied here in ELISA with chagasic sera from endemic countries. Peptide TSSApep-II/V/VI, based on a sequence common to those lineages, was widely recognised by sera from Southern Cone countries, and also unexpectedly by four samples from Ecuador; TSSApep-V/VI, which differs by a single amino acid from TSSApep-II/V/VI, was also recognised in these regions. A single TSSApep-IV reaction was seen in both Colombia and Venezuela. However, TSSApep-I was rarely and weakly recognised among the serum panel. Among the Brazilian patients, a much higher proportion of TSSApep-II/V/VI responders had ECG abnormalities than non-responders (38% vs. 17%, p<0.0001).

Rapid diagnostic tests for *L. donovani* complex infection based on rK39 antigen have lower sensitivity in East Africa compared to South Asia. The homologous sequences of rK39, and of another proposed diagnostic antigen HASPB, were amplified from a panel of East African *L. donovani* strains, and compared to published sequences, revealing significant diversity from rK39 and South Asian sequences, and non-canonical combinations of HASPB repeats. Cohorts of Indian and Sudanese VL patients were assayed by ELISA for anti-*Leishmania* IgG levels. There was an overall 46.8 – 61.7 fold lower response in the Sudanese cohort, as calculated by mean reciprocal log$_{10}$t$_{50}$ titres, regardless of antigen source, patient gender or age.

An investigation into the association of IgG subclass reactivity with VL clinical status revealed significantly elevated IgG1 levels in patients with active (pre-treatment) VL and those with post-therapy relapse compared to those deemed to be cured. A novel prototype
rapid immunochromatographic test to detect IgG1 gave > 80% of relapsed VL patients as IgG1 positive, and 80% of cured patients as IgG1 negative.
ACKNOWLEDGEMENTS - General

The research presented in this thesis was supported by the EC Framework Programme Projects ‘Comparative epidemiology of genetic lineages of *Trypanosoma cruzi*’ (ChagasEpiNet, co-ordinator Prof MA Miles, LSHTM), and ‘Syndromic approach to neglected infectious diseases at primary health care level: an international collaboration on integrated diagnosis-treatment platforms’ (NIDIAG, co-ordinator Prof M Boelaert, ITG).

In 2009, the centenary of the discoveries of Carlos Chagas, I had the great privilege to begin my doctoral research with, and receive the mentoring of, Prof. Michael A. Miles, Faculty of Infectious & Tropical Diseases, LSHTM. I have benefited greatly from expertise, reagents, technologies, and support provided from many colleagues:

**Miles group, LSHTM** Nidia Acosta, Armon Ayandeh, Rania Baleela, Duncan Bowes, Andrew Falconar, Sinead Fitzpatrick, Michael Gaunt, Marissa Gripenberg, Hannah Hafezi, Kiera Hayes, Osama Idris, Michael Lewis, Martin Llewellyn, Tegwen Marlais, Isabel Mauricio, Louisa Messenger, Emily Mills, Sara Silva Pereira, Trang Tran, Matthew Yeo.

**ChagasEpiNet partners** Prof Björn Andersson, Oscar Franzén (Karolinska Institutet, Sweden); Christian Barnabé (GEMI-IDR, France); Prof Hernan Carrasco, Maikell Segovia (Universidad Central de Venezuela); Patricio Diosque (Universidad Nacional de Salta, Argentina); Prof Alejandro Luquetti, Suelene Tavares, Liliane Siriano, Christian Rodrigues, Gabi Miranda, Rosângela Amaral (Hospital das Clinicas, Federal University of Goias, Brazil); Prof Ana Jansen, Fabiana Rocha, Samanta Xavier, Juliana Barros, André Roque, André Perreira (FIOCruz, Rio de Janeiro, Brazil); Prof Yves Carlier, Sabrina Cencig (Université Libre de Bruxelles, Belgium); Prof Mario Grijalva, Jaime Costales (Pontificia Universidad Católica del Ecuador); Prof Felipe Guhl, Juan-David Ramirez (Universidad de los Andes, Colombia); Lineth Garcia (Bolivia).

**NIDIAG partners** Prof Marleen Boelaert (Instituut voor Tropische Geneeskunde, Belgium), Prof Sayda El-Safi, Dr Osman Ahmed, Dr Osama Eisa, Dr A Saad (University of Khartoum, Sudan); Prof Shyam Sundar, Om Prakash Singh, Rajiv Srivastava, Dinesh Prajapati (Banaras
Hindu University, India); Pascal Mertens, Caroline Thunissen (Coris BioConcept, Belgium); Prof Suman Rijal, Narayan Bhattarai, Keshav Rai (BP Koirala Institute of Health Sciences, Dharan, Nepal).

**LSHTM** Ozan Gundogdu, Eloise Thompson, Carolyn Stanley, Keith Flanders.

**External** Carolyn Hyde (University College London); Sergey Litvinov (Aptum Biologicals).

**ACKNOWLEDGEMENTS – Specific contributions of others to the work described herein**

Production of synthetic peptides, experimental design & analysis, comments/editing of manuscripts: Andrew Falconar

Access to chagasic and control sera: Prof Alejandro Luquetti, Prof Mario Grijalva, Jaime Costales, Prof Felipe Guhl, Juan-David Ramirez, Lineth Garcia, Prof Hernan Carrasco, Patricio Diosque

Supply of *T. cruzi* strains and/or DNA: Michael Lewis, Louisa Messenger, Martin Llewellyn, Cristian Barnabe

Assisted phylogenetic analyses of sequences generated by candidate: Louisa Messenger, Michael Lewis, Matthew Yeo

Novel bioinformatic tools: Sergey Litvinov

Access to visceral leishmaniasis and control sera: Prof Shyam Sundar, Om Prakash Singh, Rajiv Srivastava, Dinesh Prajapati, Prof Sayda El-Safi, Dr Osman Ahemd, Dr A Saad

Production of IgG1 immunochromatographic rapid diagnostic test: Pascal Mertens, Caroline Thunissen

Students performing research work under the candidate’s supervision: Duncan Bowes, Armon Ayandeh, Marissa Gripenberg, Trang Tran, Sara Silva Pereira.

1. GENERAL INTRODUCTION

1.1 Trypanosoma cruzi and Chagas disease

Chagas disease (American trypanosomiasis) remains an important parasitic disease in the Americas. The aetiological agent, the trypanosomatid protozoan Trypanosoma cruzi, is transmitted by species of triatomine bugs and is estimated to infect at least 8 million people in the endemic region (www.who.int/mediacentre/news/releases/2007/pr36/en/) (Figure 1).

Figure 1 Distribution of Chagas disease. Endemic region indicated in purple (Morel & Lazdins, 2003).

Early symptoms may include fever, fatigue and generalised oedema, but chronic infection can lead to debilitation and death by cardiac and/or intestinal complications. The estimated disease burden in endemic countries is over 0.6 million DALYs, with around 14,000 deaths per annum (Hotez et al., 2009). Genetically diverse, T. cruzi is divided into the intra-species lineages TcI-TcVI. The association of genotype with geographical distribution is complex: TcI is found from the USA to Argentina in sylvatic cycles of transmission, with domestic infection principally north of the Amazon; TcII is found predominantly in human infections in the Southern Cone countries, and TcV and TcVI have only, as yet, been reported in Southern Cone countries. The different genotypes may also be associated with different natural transmission cycles (i.e., the insect vectors and mammalian hosts in sylvatic and domestic situations), and the varying symptoms of the disease. A key goal remains the clarification of this latter relationship. Despite recent successes in disrupting the vector-borne transmission cycle in the Southern Cone countries, no prophylactic vaccine or
satisfactory chemotherapy exists for Chagas disease, especially in the chronic phase. It threatens to emerge as a public health issue beyond the endemic region, where chronically-infected migrants are a source for parasite transmission.

1.2 *Leishmania donovani* complex and visceral leishmaniasis

The human leishmaniases exhibit a broad range of clinical syndromes, including: localised self-healing skin lesions (cutaneous leishmaniasis, CL); nasopharyngeal tissue destruction (mucocutaneous leishmaniasis, MCL); hepatosplenomegaly (visceral leishmaniasis, VL, ‘kala-azar’); post-kala-azar dermal leishmaniasis (PKDL, a sequel of VL). The different diseases are caused by infection by various species of the trypanosomatid protozoan *Leishmania* genus, acquired during bloodmeal feeding by an infected sandfly vector. The gravest form is VL; symptomatic disease is usually fatal if untreated. The great majority of the estimated 200,000 to 400,000 annual new VL cases are found in South Asia, East Africa, and Brazil (Figure 2), with 50,000 deaths per year (WHO, 2010a; Alvar *et al*., 2012).

![Figure 2 Distribution of VL. (Chappuis *et al*., 2007)](image)

VL is caused by species of the *L. donovani* complex. These are *L. donovani* in East Africa and South Asia, and in Latin America *L. infantum* (historically ‘*L. chagasi*’) imported from Europe in recent centuries. Populations most at risk are among the poorest of society, and also non-immune migrants seeking refuge from war or famine in endemic areas. Epidemics have been particularly catastrophic. The rise of HIV infection has also been followed by an increase in incidence in VL cases worldwide. No prophylactic human vaccine exists, and diagnosis is by clinical signs, demonstration of intracellular amastigote forms, or
serology. Rapid diagnostic tests based on serology (detection of presence of anti-leishmanial antibodies) have proved very sensitive in certain endemic regions, but less so in others, for reasons that hither to have been unclear.
2. LITERATURE REVIEW

2.1 Carlos Chagas and the discovery of *T. cruzi*

Carlos Chagas (1879-1934), a doctor working in Lassance, southern-central Brazil, observed that protozoan flagellates found in faeces of night-biting triatomine bugs caused experimentally infected marmosets to develop a circulating trypanosome. Originally naming them *Schizotrypanum cruzi*, he went on to find the parasites circulating in children in Lassance with an acute febrile illness (Figure 3). Subsequently, he described the life cycle and mammalian host (Chagas, 1909). Emile Brumpt (1877-1951) later showed the mechanism of parasite transmission to be through infected bug faeces.

![Image](image.png)

**Figure 3** Carlos Chagas examining baby. Lassance, Brazil c.1910 (Arquivo Iconográfico da Casa de Oswaldo Cruz, Brazil).

2.2 *T. cruzi*

2.2.1 Taxonomy

The taxonomy of *T. cruzi* is given in Figure 4. The full taxonomic designation *Trypanosoma (Schizotrypanum) cruzi* refers to those trypanosomes of the subgenus *Schizotrypanum*, which undergo intracellular multiplication in vertebrates.
2.2.2 Life cycle

The life cycle of *T. cruzi* is summarised in Figure 5.

**Figure 5** Life cycle of *T. cruzi* (CDC).
After an infected triatomine takes a blood meal, infective metacyclic trypomastigotes deposited in its faeces enter the host through the bite wound, abraded skin, or intact mucosal membranes, *e.g.*, conjunctiva, invading host cells near the inoculation site. Differentiation to intracellular amastigotes occurs. After cycles of binary replication, doubling every ~12 hrs, the amastigotes differentiate into trypomastigotes, rupture the host cell, releasing this form into the bloodstream, where they can infect various cell types and transform into intracellular amastigotes in new sites. Circulating trypomastigotes, ingested during a bloodmeal on an infected host by the triatomine, transform into epimastigotes in the vector’s midgut, where they multiply before differentiating into infective metacyclic trypomastigotes in the hindgut (Figure 6). These are eliminated with triatomine faeces and are able to infect the vertebrate host.

**Figure 6** *T. cruzi* development in the triatomine vector. [A] Ingested epimastigotes and some sphaeromastigotes in stomach. [B] Epimastigotes multiply in midgut. [C] Transformation into metacyclic trypomastigotes in rectum. (Garcia *et al.*, 2007) [D]. Epimastigotes.

### 2.2.3 Ultrastructure

A schematic of the epimastigote form of *T. cruzi* is shown in Figure 7. The single mitochondrion, which contains the kinetoplast, drives the flagellum which stems from it and extends beyond the cell. Figures 7A and 7B depict the epimastigote and trypomastigote forms respectively. The kinetoplast contains extranuclear DNA arranged in mini- and
maxicircles. The flagellum has nine pairs of peripheral microtubule doublets surrounding a central pair (Figure 7C).

Figure 7 T. cruzi ultrastructure. [A] Schematic of epimastigote form. (Docampo et al., 2005) [B] Trypomastigote has centrally positioned nucleus, and kinetoplast located towards the posterior (Teixeira et al., 2012). [C] Transversal view of thin section of flagellum of T. cruzi. Bar = 50 nm. (de Souza, 2009)

2.2.4 Vertebrate host cell invasion

Host cell invasion by T. cruzi is a multi-step process involving interaction of parasite and host cell-surface molecules. In vitro cultured trypomastigotes express surface glycoproteins of the gp85 family, which have extracellular matrix component binding capability (Yoshida, 2006). These allow the subsequent enzymatic degradation of the matrix surrounding the target host cell, enabling parasite surface molecules such as trans-sialidase
(Butler et al., 2013) to interact with, and initiate the invasion of, the host cell. Host proteins identified as interacting with T. cruzi include kinin receptor (Todorov et al., 2003) and the nerve growth factor receptor TrKa (Melo-Jorge & Pereira, 2007).

The trypomastigote becomes stably attached to the host cell, and initiates a signaling process leading to an elevation of intracellular free Ca$^{2+}$. Host cell lysosomes are recruited to migrate to the trypomastigote attachment site, fuse with the plasma membrane, and allow the parasite to enter the host cell in via a parasitophorous vacuole formed by lysosomal membranes. T. cruzi-induced Low Density Lipoprotein receptor (LDLr) upregulation in infected cells has been shown, the same paper also reporting the role of parasite-bound LDLr in lysosome trafficking and fusion to the parasitophorous vacuole (Nagajyothi et al. 2011). The acid environment of the parasitophorous vacuole favours the activity of Tc-Tox, the T. cruzi pore-forming molecule, leading to vacuole disruption. The acidic pH also stimulates trypomastigote differentiation into amastigotes, the intracellular replicative forms. After these differentiate into trypomastigotes, the host cell is ruptured, and this infective stage is released into the bloodstream. (Tan & Andrews, 2002; Manoel-Caetano & Silva, 2007)

2.2.5 Vectors

Several triatomine bug species are particularly important in human T. cruzi transmission, due to their ability to colonise human habitations and peri-domestic areas. Examples of these, along with geographic distributions, are shown in Figure 8.
Both sexes are obligate haematophages, requiring at least one blood meal prior to progression to the next of their five growth instars. The bugs are often found in domestic or peri-domestic environments, where the poor nature of the dwelling’s construction favours colonisation by triatomines (Figure 9). Triatomine species emerge from their sanctuaries in such dwellings to take a blood meal from the human inhabitants at night.
2.2.6 Other routes of infection

*Oral infection*. Infected insects, crushed during beverage preparation, have been the main source of *T. cruzi* leading to outbreaks of orally-acquired infection (Shikanai-Yasuda & Carvalho, 2011). These have often occurred in periurban and rural areas of non-endemicity. Recent instances include contamination of açai juice, the fruit of the palm *Euterpe oleracea* (Nobrega *et al.*, 2009), and contamination of a guava drink, affecting pupils and personnel at a school in suburban Caracas (Noya *et al.*, 2010; Segovia *et al.*, 2013). Murine models of oral-route infection have indicated parasite persistence in gastric mucosal epithelium, with a key role for parasite surface glycoproteins gp82 in initiating cell invasion (Yoshida, 2008).

*Congenital transmission*. A report by PAHO gives a figure of over 14,000 annual cases of congenital Chagas disease in the Americas (PAHO, 2006). In order to prevent acute neonatal infection progressing to chronic, ante-natal serological screening of ‘at risk’ pregnant women, detection of living parasites in neonates in umbilical cord or venous blood, and serology of infants over 9 months old, in conjunction with benznidazole and nifurtimox therapy, are recommended (Carlier *et al.*, 2011).

*Transfusional and organ donation*. Donation of blood or organs from infected individuals is also a route of *T. cruzi* infection. Screening of donated blood has formed part
of the Chagas disease control programmes (SECTION 1.5), and organ donation has been recognised as a route of infection in endemic and non-endemic settings (SECTION 1.4.3)

2.3 Chagas disease

2.3.1 Clinical manifestations

*Acute Phase.* Cases of the acute phase last 6-8 weeks, and are seen mainly in children, beginning with the potential development of a nodular, erythematous inflammatory response (inoculation chagoma) 1-3 weeks after the bite of the triatomine. Entry of the infective metacyclic trypomastigote form of the parasite passed in the feeding bug’s faeces into the circulation occurs through the wound, abraded skin, or via the conjunctiva. In the latter case, Romaña’s sign (conjunctivitis, unilateral palpebral oedema, and preauricular satellite adenopathy) may occur (Prata, 2001) (Figure 10A).

![Figure 10](image.png)

*Figure 10* Acute phase of Chagas disease. [A] Romañas sign exhibited in left eye of child. [B] Blood film showing tryptomastigote (circled) with flagellum. (WHO/TDR/Stammers)

Parasitaemia may be identified by direct examination of blood (Figure 10B). The majority of acute cases, however, are not recognised as such, due to the non-specific nature of symptoms (fever, fatigue, oedema), and paucity of clinical manifestations. Without treatment, around 5% of symptomatic patients die during the acute phase due to severe cardiac failure, encephalomyelitis and rarely sudden death (Prata, 2001).
**Chronic phase.** In the 2-4 months following initial infection, acute symptoms recede, with parasites rarely detected in peripheral blood. The host immune response against the parasite is not sterilizing, *i.e.*, does not destroy the first infection or subsequent challenge infections, and the host remains infected for life. The infection may remain clinically latent for decades, and most of these ‘indeterminate’ patients remain asymptomatic for life. Approximately 30% of infected patients develop the severe form of Chagas disease, in which irreversible chronic manifestations involve the heart, gastro-intestinal tract, and nervous system. Trypomastigote-infected heart muscle cells form amastigote pseudocysts (Figure 11A). When these rupture in the myocardium, an acute myocarditis occurs, with myocytolysis, vasculitis and fibrosis. A high frequency of arrhythmias is characteristic of chronic chagasic heart disease caused by the inflammatory reaction in cardiac tissue. Thinning and deficit is preferentially localised in the apex of the left ventricle (apical lesion; Figure 11B), and is particularly seen in the Southern Cone region of South America. The frequency of this lesion is related to severity of cardiomyopathy, and is accompanied by characteristic electrocardiographic changes. Sudden death occurs in over 30% of chronic cases, mainly in males around the age of 40 (Prata, 2001). Another feature is the presence of chagasic megas Syndromes in the southern part of South America. Up to 20% of patients develop functional defects in the oesophagus and colon, due to the destruction of the myoenteric nervous plexus (Dutra & Gollob, 2008). These are marked by the presence of chagasic megaoesophagus (Figure 11C) and megacolon. Dysperistalsis in the oesophagus leads to dysphagia, the most important symptom of oesophagopathy, and megacolonic syndrome often presents as obstipation. Chagas disease may be reactivated by immunosuppression, as occurs in HIV-AIDS, or during organ transplant.
**Figure 11** Chronic phase of Chagas disease. [A] Section of heart muscle (haemotoxylin & eosin stain) showing amastigotes. (WHO/TDR/Stammers) [B] (Left) Chagasic heart disease with apical aneurysm (arrowed); (Right) frontal section of same heart showing mild chamber enlargement. (Marin-Neto et al., 2007) [C] Stages of megaoesophagus: (a) anecstatic, (b) mild, (c) moderate, (d) dolichomegaoesophagus. (Prata, 2001)

The course of Chagas disease is represented schematically in Figure 12.
Figure 12 Course of Chagas disease. (Rassi Jr et al., 2009)

Parasite load, strain and tissue tropism, and host antiparasite response, autoreactivity and genetic background are thought to be implicated in the establishment of pathology in Chagas disease, and to explain the range of severity of chronic symptoms (Dutra & Gollob, 2008).

2.3.2 Diagnosis

Many of the generalised signs of infection may not lead to identification of acute Chagas disease. *T. cruzi* may be detected parasitologically in the blood in acute cases, but then the parasitaemia decreases to sub-detectable levels. In the chronic phase, xenodiagnosis - the feeding of laboratory-reared triatomines on patient blood and examination for presence of infection in the bug faeces - and blood culture have been used. In this phase, the serological tests used are listed in Table 1 (Anon., 2008).
Table 1 Serological tests used in diagnosis in chronic phase of Chagas disease.

<table>

<td>Lower sensitivity than IFA or ELISA; false positives and low reproducibility; requires cold chain</td>
</tr>
</tbody>
</table>

Current WHO recommendations are that at least two of these tests be positive for definitive serological diagnosis (WHO, 2002). Serological tests use whole cell *T. cruzi* lysates, semi-purified or recombinant antigens for the detection of anti-*T. cruzi* antibodies, which are of the IgG isotype in the chronic phase. A recent WHO comparative evaluation undertaken in Latin America on a panel of commercial serological assays (Otani et al., 2009; WHO, 2010d) found that EIA performed better than haemagglutination and particle agglutination assays, with the confirmatory use of RIPA being used as the gold standard for EIA confirmation.

Rapid diagnostic tests (RDTs) generally take the form of immunochromatographic tests, containing whole cell lysates or recombinant antigens bound onto a membrane at a ‘test’ line, plus a dye-conjugated antibody-binding protein. An example is shown in Figure 13, for the Chagas Stat-Pak Assay RDT. After the sample (whole blood or plasma/serum, depending on manufacturer instructions) is applied in its well, the addition of a larger volume of buffer allows antibodies in the sample to be bound by the dye-conjugated antibody-binding protein, and migrate by lateral flow through the membrane. If the sample contains antibodies against the bound *T. cruzi* antigen, they become localised and can be visualised as a discrete, coloured band on the ‘test’ line (shown on the right in Figure 13). The sample continues to migrate along the membrane, where an internal IgG antigen ‘control’ line is visualised, validating the test in the presence or absence of the ‘test’ line visualisation.
Figure 13 Example of RDT for Chagas disease. In this Chagas StatPak Assay are shown the outcomes if the sample is negative (left) or positive (right) for the presence of anti *T. cruzi* antibodies. Both samples have bands on the ‘control’ line, thereby validating the test reagents and results.

In a recent international multi-centre trial organised by MSF, a panel of 11 commercialised RDTs was evaluated by National Reference Laboratories in 9 countries (endemic and non-endemic) using their own serum bank plus a standard control panel (Sanchez *et al.*, 2014). Although overall performance results were reported as being lower than those described by manufacturers, six tests were recommended by the authors for screening and surveillance as RDTs (with reference laboratory confirmation). Interestingly, one of these was Chagas Stat Pak Assay, which was tested but not recommended by the authors of the WHO Latin American study described above for screening donated blood. The authors of the MSF RDT study also noted that antigenic variability in different geographical regions may play a role in RDT performance; Verani *et al.* (2009) report differences in sensitivities in two RDTs between Bolivian and Peruvian samples.

Diagnosis of cure is assessed by seroconversion (disappearance of anti-*T. cruzi* antibodies); parasite persistence is the sign of therapeutic failure, although this may be difficult to demonstrate. However, after treatment of chronic Chagas disease serological markers may take many years to disappear, so positive serology is not necessarily indicative of active infection. Lack of a proper point-of-care test to assess cure following therapy has been listed as a knowledge gap and research priority in a recent WHO report (WHO, 2012) requiring biomarker discovery and clinical validation.
Another consideration is the possible serological mis-identification of *Trypanosoma rangeli*, a closely-related but non-pathogenic organism, as a false-positive for *T. cruzi* infection (de Moraes et al., 2008), particularly when whole cell lysate is used as antigen. A recent proteomic comparison of a *T. rangeli* strain and a *T. cruzi* strain identified some candidate *T. rangeli*-specific proteins (Wagner et al., 2013). The genome of a reference *T. rangeli* strain has recently been published (Stoco et al., 2014).

2.3.3 Prevalence

Prevalence of *T. cruzi* infection in Latin America is indicated by country in Figure 14.

![Figure 14 Prevalence of T. cruzi infection in Latin America.](www.nature.com/nature/journal/v465/n7301_supp/full/nature09222.html)

Cases of Chagas disease has been identified in non-endemic regions in Europe, North America and Japan in Latin American emigrants (Gascon et al., 2009). The number of *T.
cruzi-infected individuals living in the USA has been estimated at 300,000 (Bern & Montgomery, 2009). Screening of donor blood for T. cruzi in the USA has begun recently (CDC, 2007). A WHO report on Chagas disease in Europe describes Spain as having the highest numbers of estimated cases (Figure 15; WHO, 2010c), including most of the congenital infections in babies born to Latin American mothers. Organ transplant from infected individuals has led to reports of Chagas disease in recipients, with recent cases in Spain (umbilical cord blood transplantation; Forés et al., 2007) and the USA (heart transplantation; Kun et al., 2009).

![Figure 15 Distribution of cases of T. cruzi infection in Europe. (WHO, 2010c).](image)

In the UK, there have been 44 passively diagnosed cases (D Nolder, LSHTM, Personal communication). A figure of 14000 cases of T. cruzi infection among Latin American migrants in the UK was recently estimated (WHO, 2010c).

2.3.4 Treatment and Management

No prophylactic vaccine currently exists for Chagas disease. The nitroheterocyclic compounds nifurtimox (developed by Bayer, 1967) and benznidazole (developed by Roche,
1972) have historically been the only available effective drugs for trypanocidal chemotherapy (Figure 16).

Figure 16 Chemotherapeutic agents to treat Chagas disease. (Wilkinson & Kelly, 2009)

Early treatment by oral chemotherapy during the acute phase requires daily doses for 1-4 months (nifurtimox), and 1-2 months (benznidazole), and can cause severe side-effects. In the case of nifurtimox, these are commonly manifested as gastrointestinal and neurological complications; for benznidazole, allergic dermatitis and peripheral neuropathy (Marin-Neto et al., 2009; Bern, 2011). Proposed modes of action of these drugs may be through an increase in oxidative stress in the parasite, and DNA damage (Wilkinson & Kelly, 2009). Nifurtimox and benznidazole are prodrugs, and rely on cleavage by a T. cruzi-encoded type-I nitroreductase (TcNTR) for activation to become trypanocidal agents; one mechanism of drug resistance is caused by loss of this gene or its function (Wilkinson et al., 2008; Mejia et al., 2012). A multinational clinical trial of benznidazole to determine whether trypanocidal treatment improves prognosis in chronic chagasic heart disease patients (the BENEFIT project) is ongoing (Marin-Neto et al., 2009; http://clinicaltrials.gov/ct2/show/NCT00123916). The anti-fungal triazoles posaconazole and ravuconazole, ergosterol biosynthesis inhibitors, have recently been used in clinical trials as novel trypanocides. However, posaconazole did not show efficacy in adult South American patients with chronic Chagas disease residing in Barcelona (Molina et al., 2014). Ravuconazole, administered in its prodrug form E1224, in trial in chronic indeterminate phase patients in Bolivia (http://clinicaltrials.gov/ct2/show/NCT01489228?), also has not shown promising results.

An important consideration is that drug tests should consider the genetic diversity of T. cruzi (Zingales et al., 2014), further described in SECTION 2.5.
Surgical treatment for megacolon (Nahas et al., 2009) and megaoesophagus is important in chronic cases.

2.4 Control programmes

In recent decades, a number of initiatives have been supported by PAHO with the aim of controlling the spread of *T. cruzi* transmission. These programmes have been directed towards prevention of transmission by transfusion of donated blood, and by residual insecticide spraying of dwellings against the triatomine vectors. These are operated through subregional initiatives, as shown in Figure 17.

![Subregional vector control initiatives against T. cruzi transmission.](nature.com/nature/journal/v465/n7301_supp/full/nature09222.html); PAHO.

Some key achievements of INCOSUR are described in Figure 18.
In 2008, Guatemala was the first country in Central America to be certified by IPCA as being free from transmission by *R. prolixus*, the main Central American domiciliated vector, followed by Mexico in the same year, El Salvador in 2010, Nicaragua, Honduras and Costa Rica in 2011, and Belize in 2012 (Hashimoto and Schofield, 2012; PAHO, 2012).

### 2.5 *T. cruzi* ecology and epidemiology

Chagas disease is an anthropozoonosis, in that *T. cruzi* was initially a parasite of sylvatic animals, and became a human infection after triatomine bugs adapted to invading human settlements for a food source. Unlike birds and reptiles, all mammals are considered at risk from *T. cruzi* infection, and are thus potential natural reservoirs. The recognition of a disparate geographic distribution of chagasic disease syndromes, and aspects of *T. cruzi* biology, led in the 1970s to the first description of distinct parasite ‘strain-groups’ in Brazil, derived from human/domiciled animal infections and from sylvatic opossums and triatomines (Miles *et al*., 1977). Using a MLEE approach, the electrophoretic patterns of various *T. cruzi* enzymes revealed two combinations of isoenzyme pattern among the stocks investigated, leading to the initial subdivision of *T. cruzi* into zymodemes, or enzyme groups. Later molecular (DNA–based) techniques, such as analysis of the spliced-locus intergenic region (SL-IR) of the miniexon gene and 24Sα rDNA (Souto *et al*., 1996), reinforced the dichotomous view of *T. cruzi*. On the basis of the accumulated data, *T. cruzi* was classified
into two principal groups, TcI and TcII (Anon., 1999). TcII was subsequently further divided into TcIIa-e (Brisse et al., 2000) based on genetic markers. According to the latest recommendations (Zingales et al., 2009), the six lineages are now recognised as TcI - TcVI. Lewis et al. (2011) report the recent, anthropic generation of the TcV and TcVI lineages, resulting from a hybridisation between TcII and TcIII. A scheme for T. cruzi lineage evolution is depicted in Figure 19.

![Figure 19 Schematic of proposed T. cruzi lineage evolution. (Westenberger et al., 2005)](image)

Gaunt et al. (2003) used distinct ‘parent’ strains of T. cruzi transfected with different drug resistance markers in co-passage through mammalian cell culture to produce hybrid double-resistant clones in vitro, showing that the parasite has an extant capacity for genetic exchange, involving the fusion of parental genotypes, loss of alleles, and homologous recombination.

The association of lineages with geographical distribution is complex (Figure 20). TcI is found as far north as the USA, whereas TcII, TcV, and TcVI predominate in the Southern Cone countries, although TcII infection has been reported in Colombia (Zafra et al., 2008). Recent evidence has shown TcIII to exist in armadillos from Venezuela to Paraguay (Llewellyn et al., 2009b), but is rare in humans. Carrasco et al. (2012) report around 20% of human-isolated T. cruzi in Venezuela to be TcIV. TcI is linked to chagasic cardiomyopathy in central and northern South America, whereas TcII/TcV/TcVI in the Southern Cone correlate in distribution with cardiomyopathy and the presence of chagasic megasyndromes of the
colon and oesophagus. An important goal remains to clarify the relationship between parasite genotype and clinical outcome.

Figure 20 Approximate distributions of *T. cruzi* lineages, with cycles of transmission. (M Llewellyn, LSHTM)

Yeo *et al.* (2005) proposed broadly that TcI co-evolved with opossums (*Didelphis* spp.) or *Rhodnius* in the palm tree niche, whereas, TcIII co-evolved with armadillos (*Dasypus* spp.) in the terrestrial niche (Figure 21). They further suggest that respective historical arboreal and terrestrial ecologies of these hosts explain intraspecific diversity of *T. cruzi* in South America, and the separate origins for Chagas disease in the northern and southern parts of the continent.
Figure 21 Mammalian hosts of *T. cruzi*. [A] Opossum *Didelphis marsupialis*. (Universidade Federal de Minas Gerais, Brazil). [B] Nine-banded armadillo *Dasypus novemcinctus*. (National Biological Information Infrastructure, USA)

The different lineages are associated with different ecological niches, natural transmission cycles (sylvatic or domestic), and Chagas disease, as summarised in Table 2.

Lewis et al. (2009) used PCR-AFLP and -RFLP protocols to develop a system for lineage identification (Figure 22).

**Figure 22** Triple assay for discriminating *T. cruzi* lineages. (Lewis et al, 2009). LSU rRNA = large subunit ribosomal RNA gene; HSP60 = heat shock protein 60 gene; GPI = glucose-6-phosphate isomerase. Corresponding current and previous lineage designations are shown.

The phylogenetic relationships between lineages have been explored by the use of multilocus sequence typing (MLST) targets. Concatenated sequences from four loci were used to group a panel of *T. cruzi* isolates into clades, as shown in Figure 23 (Yeo et al, 2011). By this analysis, two groupings, one comprised by TcII, TcV and TcVI, and the other by TcI, TcIII and TcIV emerged.
Even within individual lineages, the situation appears more complex than previously understood. Typing based on Tcl SL-IR has revealed sub-groups Tcl-a (Falla et al., 2009; Cura et al., 2010; Tomasini et al., 2010). Llewellyn et al. (2009a) described human isolates restricted to two distinct groups within a broad panel of Tcl strains by multilocus microsatellite typing (MLMT) typing. Ocaña-Mayorga et al. (2010), described two discrete populations of Tcl, one predominantly domestic/peri-domestic, the other silvatic, in Ecuador.

Of interest is the different tissue tropisms of different lineages, which has been reported with analysis of T. cruzi DNA from different organs using patient samples taken from heart and oesophagus (Vago et al., 2000) or blood and heart (Burgos et al., 2010);...
recent murine studies have also reported different myocarditis patterns (Rodriguez et al., 2014).

Recently, a new genotype of *T. cruzi* restricted to bats, called TcBat, related to TcI, has been described from Brazil (Marcilli et al., 2009), Panama (Pinto et al., 2012) and Colombia (Ramirez et al., 2013).

However, of crucial importance are the current limitations of identifying infecting lineage: i) direct genotyping of *T. cruzi* by direct PCR on blood or cultured isolates is only feasible when there is a sufficient circulating parasitaemia, which is confounded by the sequestration of the parasite in host tissues in the chronic phase, possibly in a lineage-dependent manner, and the prospect of lineage selection bias during culture; ii) current serological methods to detect antibodies against *T. cruzi* give no information on infecting lineage(s) and are not designed for that purpose.

### 2.6 *T. cruzi* reference genome sequencing

Table 3 lists the *T. cruzi* strains representative of their lineages for which reference genomes have been sequenced.

a accessible via http://tritrypdb.org; b bat-associated subspecies
As it had been well characterised experimentally, CL Brener (TcVI) was chosen as the strain for the first *T. cruzi* genome sequence (El-Sayed et al., 2005). As shown in Figure 19, TcV and TcVI are now understood to be hybrids of TcII and TcIII; thus for the CL Brener genome the two contributing haplotypes were named Esmeraldo-like (TcII) and non-Esmeraldo-like (TcIII). Additionally, over 50% of this genome was found to consist of repeated sequences. The genome of a representative Tcl strain, Sylvio X10/1, was subsequently sequenced as a non-hybrid, evolutionarily distinct, comparison (Franzén et al., 2011). The Tcl Sylvio X10/1 haploid genome was estimated to be smaller than that for TcVI CL Brener (44 Mb vs. 55 Mb). The two genomes were reported to have highly conserved gene synteny and core gene complement, but although 6 ORFs in CL Brener were not found in Sylvio X10/1, no Sylvio X10/1-specific genes were identified. The comparative genomic analysis also found a differential expansion in sequences corresponding to surface antigen repertoires and other multicopy gene families, with the CL Brener genome estimated as having ~6Mb of extra haploid sequence related to these multigene families compared to Sylvio X10/1. As surface molecule genes are major contributors to the repetitive nature of the CL Brener genome, this was concluded by the authors to underlie most of the haploid genome size difference between the two *T. cruzi* lineages, having the potential to enhance functional plasticity.

2.7 Research needs: Chagas disease

As described herein, *Trypanosoma cruzi* is now understood to be a complex of diverse genotypes, possessing the capacity for genetic exchange, and displaying differing geographical distributions in terms of Chagas disease symptoms and severity, sylvatic hosts, and transmission cycles. Control programmes underway in recent years have the potential to achieve even greater successes in interrupting transfusional and vector-borne transmission. Relevant to this project, Coura (2007) lists a ‘top ten of Chagas disease needs’ including ‘3. To improve a specific and fast test for Tcl-TcVI infections’ and ‘4. To standardize the techniques for serological diagnosis and control of cure evaluation’.

Thus, there is the key question of the identification of an individual’s history of *T. cruzi* lineage infection. As described above, molecular (DNA) techniques have their
limitations, so an indirect approach is required. Such a method would be based on the identification of lineage-specific antigens and the development of a serological assay to exploit differential antibody responses to these.

Aims and objectives for the work on *T. cruzi* presented in this thesis are described in SECTION 3.1.

### 2.8 Discovery of *Leishmania*

In 1903, William Leishman (1865-1926) and Charles Donovan (1863-1951) both reported observations of intracellular bodies in samples from ‘kala-azar’ patients in India (Figure 24; Leishman, 1903; Donovan, 1903). In the same year, Ronald Ross (1857-1932) gave the name *Leishmania donovani* to these intracellular parasite stages (Ross, 1903). Person-to-person transmission was later demonstrated to be mediated by the sandfly (Swaminath *et al*., 1942).

**Figure 24** Leishman and Donovan. [Left] William Leishman. [Centre] Charles Donovan. (both http://dna.kdna.ucla.edu/parasite_course-old/leish_files/subchapters/Historical.htm). [Right] Spleen smear preparation from patient described in Leishman (1903).
2.9 *Leishmania* spp.

2.9.1 Taxonomy

The taxonomy of *Leishmania* to genus level is shown in Figure 4. *Leishmania* are classified into the two subgenera *Leishmania* (Leishmania), and *Leishmania* (Viannia). Taxonomy to species level is shown in Figure 25.

![Figure 25 Taxonomy of Leishmania. * = species status under discussion. (WHO, 2010b)](image)

2.9.2 Life cycle

The life cycle of *Leishmania* is summarised in Figure 26.
Leishmania promastigotes are transmitted to humans through the proboscis of female sandflies (Phlebotomus spp. and Lutzomyia spp. in the Old and New World respectively) during bloodmeal feeding. Following internalisation by local dermal macrophages and dendritic cells, flagella are lost, and transformation into proliferative amastigote forms leads to cell lysis, and phagocytosis by other cells. Upon taking a bloodmeal containing infected host macrophages, amastigotes are liberated in the sand fly gut, transform into promastigotes, and migrate to the proboscis (described in more detail in SECTION 2.9.3).

2.9.3 Vectors

The vectors for L. donovani are Phlebotomus argentipes in South Asia, Phlebotomus martini and Phlebotomus orientalis in East Africa, and Lutzomyia longipalpis for L. infantum in the Americas (Figure 27).
Figure 27 Sandfly vectors of *Leishmania*. [A] *Phlebotomus* sp. (Old World vector). (CDC) [B] *Lutzomyia longipalpis* (New World vector).

(*www.plospathogens.org/article/fetchObject.action?uri=info%3Adoi%2F10.1371%2Fimage.ppat.v05.i08.g001&representation=PNG_S*)

*Leishmania* are classified into the two subgenera *Leishmania* (*Leishmania*) and *Leishmania* (*Viannia*). In *Leishmania* (*Leishmania*), promastigote development occurs in the sandfly midgut (suprapylian development), whereas it occurs in the hindgut (peripylian development) for *Leishmania* (*Viannia*). Species of the subgenus *L*. (*Viannia*) are restricted to the New World. Suprapylian development, the better understood of the two, is briefly described here (Kamhawi, 2006; Bates, 2007). *Leishmania* amastigotes ingested by the anthropophilic sandfly during bloodmeal feeding transform first into procyclic promastigotes in the blood bolus, then into motile nectomanad promastigotes (Figure 28). These migrate along the midgut epithelium by binding of surface lipophosphoglycan to a receptor in the sandfly gut. Subsequent transformation into replicative leptomonad promastigotes in the anterior midgut precedes differentiation into non-replicative infectious metacyclic promastigotes and also haptomonad promastigotes, which attach to and plug the opening of the stomodeal valve. Promastigote secretory gel produced by leptomonads fills the thoracic midgut limen; the resulting ‘blocked fly’ effect enhances regurgitation of metacyclic promastigotes into the host during bloodmeal feeding (Rogers *et al.*, 2004).
2.10 Visceral leishmaniasis

2.10.1 Clinical manifestations

Following infection from a female sandfly, the incubation period can range from 10 days to over 1 year, and usually disease onset is gradual. Common symptoms are fever, malaise, shivering/chills, weight loss, anorexia and discomfort in the left hypochondrium. Clinical signs are non-tender splenomegaly, sometimes with hepatomegaly, wasting and pallor of mucous membranes (Figure 29A). Lymphadenopathy may be present (particularly in Sudan) and be the only clinical manifestation. Darkening of the skin of the face, abdomen, hands, and feet may be found in India (Hindi: kala-azar = black fever). In Sudan, a *Leishmania*-containing cutaneous nodule or ulcer or a mucosal lesion may be present. Signs of malnutrition (oedema, skin and hair changes) develop as the disease progresses. In advanced stages, intercurrent infections by other pathogens are common (WHO, 2010b). Post-Kala Azar Dermal Leishmaniasis (PKDL), characterized by a hypopigmented macular,
maculopapular, and nodular rash, may occur in patients who are cured of VL and otherwise well (Figure 29B).

**Figure 29** Clinical manifestations of VL. [A] Splenomegaly. (www.sciencephoto.com) [B] PKDL (www.who.int/leishmaniasis/Visceral_Leishmaniasis_hr.jpg)

PKDL is found in both East Africa and South Asia, with differing epidemiological features, as listed in Table 4 (Zijlstra et al., 2003).

**Table 4** Epidemiological features of PKDL in Sudan and India. (Zijlstra et al., 2003)

PKDL may have role in maintaining a reservoir population of *L. donovani*, contributing to disease persistence in the community. The inter-relationship between manifestations of *Leishmania* infection in Sudan is shown in Figure 30 (Zijlstra et al., 2003).
Figure 30 Inter-relationship between manifestations of *Leishmania* infection in Sudan. Line thickness corresponds with likelihood of occurrence. (From Zijlstra et al., 2003)

Elevated levels of the immunosuppressive cytokine interleukin-10 (IL-10) in the serum, and elevated IL-10 mRNA in spleen or bone marrow, have been often reported in VL (Nylen and Sacks, 2007); IL-10–neutralising monoclonal antibodies promoted amastigote clearance *ex vivo* in splenic aspirate cells from VL patients (Gautum et al., 2011). There is a mixed Th1/Th2 response in human VL (WHO, 2010b).

2.10.2 Diagnosis

Clinically suspected cases are those exhibiting fever for more than 2 weeks and splenomegaly in the absence of malaria (WHO, 2010b). Parasitological diagnosis, by demonstration of amastigote in lymph node, spleen, or bone marrow tissue smear, is the definitive diagnosis (Figure 31).
Figure 31 *L. donovani* amastigotes inside infected macrophage. Light micrograph of spleen tissue section. (www.sciencephoto.com).

Serological (anti-*Leishmania* antibody) tests include ELISA, IFAT, and DAT (Srivastra *et al.*, 2011). For the last few years, the RDT for VL widely used has been the rK39 ICT, based on a kinesin-related gene product, LcKin, identified by screening a Brazilian *L. infantum* (*L. chagasi*) genomic library with serum of an *L. donovani* patient (Burns *et al.*, 1993). A part of the coding sequence, comprising a 46 aa region followed by 6.5 x 39 aa repeats, forms the recombinant diagnostic protein rK39, used in the RDT bound on an ICT strip. The presence of anti-*Leishmania* antibodies in the patient sample can be visualised in a few minutes after application by the presence of a coloured band on the test strip, in the same manner as described in Section 2.3.2. An example for the rK39 RDT (BioRad Laboratories) used with Sudanese VL sera is shown in Figure 32.

![Figure 32 rK39 RDT for VL. Sudanese sera were applied to the RDT. The presence of a band at the L line indicates the presence of anti-*Leishmania* IgG. NEHC = non-endemic healthy control.](image-url)
In recent multicentre evaluations, the use of the rK39 ICT RDT reported less success in East Africa than in the Indian subcontinent for point-of-care diagnosis of VL (Tables 5 & 6; Boelaert et al., 2008; Cunningham et al., 2012).

**Table 5** Boelaert et al., 2008: Prevalence in the test sample and sensitivity and specificity of rK39 dipstick (with 95% CI).

Underlying explanatory factors for this differential regional sensitivity may reside in molecular divergence between East African *L. donovani* kinesin gene homologues and the Brazilian *L. infantum (L. chagasi)*-derived rK39 sequence and/or may be due to differential immunocompetence and antibody levels produced among African and Asian human populations.
The first two of the 39 aa repeats of Sudanese *L. donovani* kinesin homologue LdKin (Gerald *et al.*, 2007), flanked by sequences of the *L. donovani* antigens HASPB1 and HASPB2 (Alce *et al.*, 1999), comprise rK28 (Figure 33), a novel synthetic recombinant protein for diagnosis of VL, designed to be an improvement on rK39 (Pattabhi *et al.*, 2010, Vaish *et al.*, 2012). HASPB proteins are expressed on the surface of infective promastigotes and amastigote. The first 3 x 14 aa repeats of HASPB1 are incorporated into rK28, along with the complete ORF of HASPB2, which includes three imperfect consecutive repeats, 2 x 14 aa and 1 x 13 aa.

**Figure 33** Synthetic gene rK28. Comprised by repeats of HASPB proteins flanking Sudanese-derived kinesin repeats.

An additional aspect of the current serological tests is that they may give positive results post-cure and so cannot readily diagnose relapse, and can also indicate the presence of anti-leishmanial antibodies in asymptomatics living in endemic areas, but with no VL history (WHO, 2010b). A large Indian/Nepalese population study reported an association between higher DAT and/or rK39 titres and risk of progression from asymptomatic to symptomatic VL (Hasker *et al.*, 2014); in a long-term follow-up of 55 rK39 seropositive asymptomatic cases in India 69% developed VL and 31% remained asymptomatic (Singh *et al.*, 2002). The proportion of seropositive asymptomatic individuals that progresses to symptomatic VL has been reported to vary between endemic regions, as shown in Table 7. Currently there is no rapid diagnostic test that determines or predicts which asymptomatic carriers will progress to active VL.
Table 7  Asymptomatic progression to VL. Reports of the proportions of asymptomatic seropositive individuals who either remain symptom-free or do progress to symptomatic VL are expressed as ratios.

2.10.3 Treatment and management

Historically, the standard first-line chemotherapeutic agents to treat VL have been the pentavalent antimonials sodium stibogluconate and meglumine antimoniate, administered by injection, although development of resistance to antimonials has emerged in India (Chakravarty & Sundar, 2010), possibly caused by chronic exposure to arsenic in drinking water (Perry et al., 2013). More recent anti-leishmanials include amphotericin B, paromomycin, and miltefosine (WHO, 2010b) (Figure 34).
In South Asia, amphotericin B in liposomal formulation (AmBisome) is the preferred treatment, followed by combination therapies (AmBisome with miltefosine or paromomycin, or miltefosine with paromomycin) (WHO, 2010b). The primary target for amphotericin B is the surface membrane ergosterol (human cells have cholesterol as their major surface membrane sterol), thus parasite destruction can be achieved without amphotericin B uptake by the host. In East Africa, pentavalent antimonials with paromomycin or in combination or monotherapy remain the preferred treatment choices (WHO, 2010b).

According to a WHO/TDR publication, VL treatment outcomes are assessed twice, an initial outcome on the last day of drug treatment, and a final outcome six months after the last drug was taken (WHO, 2010e). The main outcomes, as listed therein, are given in Table 8.
Table 8 Treatment outcomes in VL (WHO, 2010e).

</table>

However, Rijal et al., (2013), in following up miltefosine–treated patients for up to 12 months after completion of therapy found a relapse rate of 20% (24/120 patients) in their studied cohort in Nepal.
As shown in Table 8, criteria for assessing cure after VL therapy are clinical. The requirement for an established biomarker of cure in VL, its clinical validation and incorporation into a point-of-care test have been identified as knowledge gaps and research priorities in a recent WHO report (WHO, 2012).

2.11 Control strategies

In 2005, a regional strategic framework for VL elimination was agreed by the endemic countries of India, Nepal, and Bangladesh, with the target to reduce annual incidence to < 1/10,000 population at district/sub-district level by 2015 (WHO, 2005). It describes the following factors as favourable for VL elimination: man is the only reservoir host; P. argentipes is the only known vector; availability and effectiveness of oral miltefosine; availability of reliable rK39 tests; past effectiveness of indoor residual spraying to control vector; political commitment; focusing of elimination efforts in endemic districts. However, the following constraints are mentioned: incomplete or inappropriate treatment from private doctors/quacks [sic]; delay in treatment favouring continued transmission; resistance to antimony drugs; persistence of reservoir in undetected and untreated PKDL; summer outdoor sleeping exposes to peri-domestic vectors; expense of treatment for poorest people.

Indoor residual spraying of organochlorines (e.g., DDT) has been the main strategy to control endophilic sandfly vectors in South Asia (WHO, 2011). Preparedness for, rapid assessment of, and response to, epidemic outbreaks has also described as a component of control strategies (WHO, 2010b).

2.12 L. donovani complex population structure

MLEE has been the ‘gold standard’ for Leishmania typing to species level; the Montpelier system (MON) is based on 15 enzymes (Rioux et al., 1990). Drawbacks of MLEE typing come from the need to have a large culture of parasite, protein electrophoresis equipment, and the reliance on electrophoretic mobilities of proteins that does not resolve individual amino acid polymorphisms (conserved or non-conserved) caused by coding DNA
changes. More recently, molecular biology techniques based on MLST (Mauricio et al., 2006; Zemanova et al., 2007) and MLMT have been used to provide greater resolutive power for the *L. donovani* complex. Lukeš et al. (2007) showed that the genetic structure of *L. donovani* complex is determined mainly by geography rather than MLEE-based taxonomy or clinical outcome, and proposed an evolutionary hypothesis for the origin and dispersal of *Leishmania*. (Figure 35A,B). The evolution of *Leishmania* was proposed to have taken place in South America ~46-36 mya (Figure 35A). Subsequent dispersal via the Bering land bridge was into Asia, where, 25-15 mya, the ancestor of *L. donovani* complex diverged from other species. Further dispersal led to the emergence of *L. infantum* ~1 mya in Central Asia and moving into Europe, while *L. donovani* entered East Africa and South Asia. *L. infantum* was introduced to the Americas from Iberia by human activities multiple times during the last 500 years; historically this has been called *L. chagasi* (Kuhls et al., 2011). When New World *Lutzomyia* became competent vectors for these parasites, VL was thus established in this region. In this thesis and its annexes, the term ‘*L. infantum* (*L. chagasi*)’ is used to describe these parasites.
Figure 35 L. donovani complex population structure, evolution and dispersal. [A] Proposed model of *Leishmania* evolution and dispersal. MYA = millions of years ago. [B] Genotype is strongly correlated with geographical origin (Lukes *et al.*, 2007). [C] MLMT identifies six populations (Kuhls *et al.*, 2007).

Kuhls *et al.* (2007) used MLMT to define six genetically distinct populations of *L. donovani* complex in VL endemic regions (Figure 35C), and reported that allelic diversity in Africa, although lower than in the Mediterranean region, was greater than in India. Another MLMT study showed a high degree of homogeneity among South Asian *L. donovani* (Alam *et al.*, 2009).

Hybrids and genetic exchange between *Leishmania* of the same species, and between different species, have been described naturally and experimentally (Tables 9 and 10).
Table 9 Natural hybrids of *Leishmania* spp.

The *L. infantum* reference genome size was reported as 32.1 Mb (Peacock *et al.*, 2007; Rogers *et al.*, 2011). A comparison of the three hither-to sequenced genomes revealed 5 *L. major*-specific, 26 *L. infantum*-specific, and ~47 *L. braziliensis* specific genes (Peacock *et al.*, 2007). Downing *et al.* (2011) published an assembled draft of the reference *L. donovani* genome strain, BPK282/0 cl4 originating from Nepal, which was chosen on the basis of being antimonial-sensitive and representative of the most common microsatellite group in South Asia (as identified by Alam *et al.*, 2009). The genome size was 32.4 Mb, and
annotated by identifying orthologous genes from the *L. infantum* genome. Although *L. donovani* diversity in the region is low, the genome sequencing of an additional 16 clinical *L. donovani* strains from India and Nepal resolved a population structure beyond that found with MLMT.

### 2.14 Research needs: visceral leishmaniasis

The *Expert Committee Report on the Control of the Leishmaniases* (WHO, 2010b) describes laboratory research needs for VL, of which the most relevant to this project is ‘research and development of rapid tests for the diagnosis of VL and tests for cure based on antigen and nucleic acid detection.’
3. AIMS AND OBJECTIVES

3.1 Trypanosoma cruzi and Chagas disease

Aim: To analyse molecular diversity within *T. cruzi*, identify lineage-specific antigenic epitopes, and apply them to determine serologically an individual’s history of exposure to *T. cruzi* lineages. Objectives:

1) compare inter-lineage diversity in antigen genes by molecular analysis of the surface mucin TSSA, across a panel of strains encompassing *T. cruzi* genetic and ecological diversity [ANNEX 1];

2) development of a *T. cruzi* lineage-specific serology: design and use of synthetic peptides, based on the identified lineage-specific TSSA sequences, in ELISAs for differential serology with human chagasic sera [ANNEX 2].

3.2 *L. donovani* complex and visceral leishmaniasis

Aim: To determine the factors underlying the reported lower levels of sensitivity of rapid diagnostic tests among East African compared to South Asian human populations. Additionally, IgG subclass responses among VL patients of different clinical status are investigated as a potential biomarker. Objectives:

3) analyse the molecular diversity of diagnostic kinesin and HASPB antigens: PCR amplification and sequencing of kinesin and HASPB genes across a panel of East African *L. donovani* strains; comparative geographical analysis with reference to GenBank-accessible sequences [ANNEX 3];

4) compare Indian and Sudanese VL patient serological responses: production of whole cell lysates of representative Sudanese and Indian *L. donovani* strains; compare differential anti-*Leishmania* IgG responses between Indian and Sudanese VL patient cohorts [ANNEX 4];

5) analyse IgG subclass responses in Indian and Sudanese VL patients: compare IgG subclass profiles in patients with different clinical status [ANNEX 5];
6) adapt anti-\textit{Leishmania} IgG1 detection to a lateral flow RDT for application at point-of-care [\textbf{ANNEX 5}].
4. MATERIALS AND METHODS

Descriptions of all reagents and protocols are described in the relevant publication(s) in Section 5 ANNEXES. Commonly used techniques are described here.

4.1 Parasite strains

*Trypanosoma cruzi*: Strains encompassing lineages TcI-TcVI used in this project are listed in ANNEX 1 Bhattacharyya et al., 2010 Table 1.

*Leishmania donovani* complex: Strains used in this project are listed in ANNEX 3 Bhattacharyya et al., 2013 Table 1.

4.2 Oligonucleotide sequences

Table 12 lists the oligonucleotides used as PCR and internal sequencing primers in ANNEXES 1, 2 & 3. All oligonucleotides synthesised by Eurofins MWG Operon.

**Table 12 Oligonucleotides used as PCR and internal sequencing primers.**

Following 25 x cycles, comprising steps at 96 °C for 30 secs, 50 °C for 20 secs, and 60 °C for 4 mins, the resulting extension products were purified. Reactions were transferred to 1.5 ml tubes on ice, containing 32 μl of 95% EtOH and 8 μl ddH$_2$O. Following 15 min incubation, the samples were spun at 13000 rpm in a bench top microfuge for 20 mins. The pellets were washed by 50 μl of 70 % EtOH, and dried at 90°C for 1 min. Sequencing was performed on an ABI3730 machine (Applied Biosystems). Sequencing analysis and alignments were performed using Bioedit software (Hall, 1999).

**4.4 Peptide synthesis**

‘In-house’ peptide synthesis was performed in collaboration with Dr A. Falconar, LSHTM. The automated systems used were ‘SMPS350 Peptide Synthesiser’ (Zinsser Analytic), and an ‘Apex396 Peptide Synthesiser’ (Aapptec). Additionally, peptides were produced commercially by Genosphere Biotechnologies. A detailed description of the synthesis and purification of peptides, from Dr Falconar, is given in ANNEX 2 Bhattacharyya et al., 2014. A brief overview of the synthesis process, based on the sequential addition of amino acid residues (initially protected at the α-amino and R side chains) to a solid phase support in the overall direction C → N, is given here (Figure 36).
A C-terminal cysteine residue linked to resin was used to prime the synthesis of each peptide. After removal of the N-α-protecting group by piperidine, subsequent amino acids were coupled. DMF was used in washing steps. A PEG spacer was coupled after the last amino acid residue (always glycine), and a terminal biotin group was added to each peptide. R-side chain deprotection and cleavage from the resin was then done. Thus, the final composition of the synthesised peptide is depicted in ANNEX 2 Bhattacharyya et al., 2014 Figure 1A. Following cleavage from the resin, peptides were purified by reverse-phase HPLC. Eluted peptide fractions were freeze-dried and stored at -85 °C.

### 4.5 Sources of human samples

Chagas disease: Hospital das Clinicas, Goiânia, Brazil; Universidad Mayor de San Simon, Cochabamba, Bolivia; Universidad Nacional de Salta, Argentina; Universidad Central de...
Venezuela, Caracas, Venezuela; Universidad de los Andes, Bogotá, Colombia; Pontificia Universidad Católica del Ecuador, Quito, Ecuador.

VL: Banaras Hindu University, Varanasi, India; University of Khartoum, Sudan.

4.6 ELISA

Chagas disease: Protocols for confirming boitinylation of synthetic peptides (a proxy for peptide integrity) and performing lineage-specific serology are given in ANNEX 2 Bhattacharyya et al., 2014

VL: Protocols for comparative serology of Indian and Sudanese VL plasma, and IgG subclass in different clinical states, are given, respectively, in ANNEX 4 Bhattacharyya et al., 2014 and ANNEX 5 Bhattacharyya et al., 2014.

Presented papers

Oral presentations and posters

Key points, novel results and implications

- The *T. cruzi* surface mucin trypomastigote small surface antigen (TSSA) had been previously described as displaying sequence dimorphism between Tcl and the then grossly-described TcII (now TcII-TcVI) lineages, and differential serology based on the antigenic properties of these sequences had led those authors to conclude that Chagas disease is due to infection by ‘TcII’ only (Di Noia *et al.*, 2002).

- Here, the diversity of the TSSA gene was examined across a panel of *T. cruzi* isolates from Tcl-TcVI lineages, encompassing the geographical and ecological range of this species.

- A greater diversity in the TSSA coding region, reflected in the predicted amino acid sequence, was identified. All Tcl strains possessed their previously described sequence in the polymorphic region, whereas all TcII, TcV, and TcVI strains shared a common sequence, with TcV and TcVI strains possessing an additional haplotype coding for a single amino acid point substitution, not previously reported. TcIII and TcIV were revealed to contain their own lineage-specific sequences, also reported here first.

- Analysis of the TSSA coding sequences among the panel inferred greater phylogenetic affinities of TcIII and TcIV to Tcl than to TcII, TcV or TcVI, in agreement with published multilocus studies; a high ratio of non-synonymous to synonymous nucleotide substitutions (ω = 1.233) indicated that the TSSA gene has been under positive selection pressure.

- Thus the demonstration here of a greater diversity of lineage-specific TSSA epitopes within TcII–TcVI has implications for seroepidemiological studies of Chagas disease based on this antigen.
**Candidate’s contribution:**

The candidate performed all the PCRs, gel electrophoresis, DNA sequencing preparation, sequence alignment, and most of the RFLP assays, of the TSSA gene as described in this publication. The candidate prepared the first draft of the manuscript, which was accepted for publication by *Int J Parasitol* in January 2010 following academic peer review.

(Double-click on image to view embedded document)

The results described above were then applied to the design and use of synthetic peptides for *T. cruzi* lineage-specific serology, as described in the following section (ANNEX 2 Bhattacharyya *et al.*, 2014).
COVER SHEET FOR EACH 'RESEARCH PAPER' INCLUDED IN A RESEARCH THESIS

Please be aware that one cover sheet must be completed for each 'Research Paper' included in a thesis.

1. For a 'research paper' already published

1.1. Where was the work published? .........................................................

1.2. When was the work published? ...........................................................

1.2.1. If the work was published prior to registration for your research degree, give a brief rationale for its inclusion

Subject: REQUEST TO USE COPYRIGHTED MATERIAL IN THESIS

Dear Sir/Madam

I am currently studying for a research degree at London School of Hygiene and Tropical Medicine.

I am contacting you to seek permission to include the following material within the electronic version of my PhD thesis:

Article title: Analysis of molecular diversity of the Trypanosoma cruzi trypomastigote small surface antigen reveals novel epitopes, evidence of positive selection and potential implications for lineage-specific serology
If you are not the rights holder for this material I would be grateful if you would advise me who to contact.

The thesis will be made available within LSHTM Research Online http://researchonline.lshtm.ac.uk/ our institutional repository. The repository is non-commercial and openly available to all.

Yours sincerely
Tapan Bhattacharyya
Analysis of molecular diversity of the *Trypanosoma cruzi* trypomastigote small surface antigen reveals novel epitopes, evidence of positive selection and potential implications for lineage-specific serology

1. Introduction

Chagas disease, marked by life-long chronic infection with *Trypanosoma cruzi*, remains a major parasitic disease in Latin America. Genetically heterogeneous, *T. cruzi* is divided into six discrete typing units (DTUs), most recently grouped as TcI–VI. The trypomastigote small surface antigen (TSSA) of *T. cruzi* has been described as the only known serological marker to identify infection by TcII–VI, as distinct from TcI. Here, by comparative analysis of a cohort of 25 reference strains representing all the known DTUs, we show that TSSA intra-specific diversity is greater than previously reported. Furthermore, TcII and IV TSSA PCR products are, contrary to expectation, both digested by PvuII, revealing a more nuanced genotyping pattern. Amino acid sequence diversity reveals that the TSSA epitope considered to be serologically characteristic of TcII–VI is restricted to TcII, V and VI, but not of III or IV, and that the diagnostic peptide described as Tc-specific shares key features with TcIII and IV. Notably, TSSA sequences inferred greater phylogenetic affinities of TcIII and IV to Tc than to TcII, V or VI. A high ratio of non-synonymous to synonymous nucleotide substitutions (*ω* = 1.233) indicates that the TSSA gene has been under positive selection pressure. The demonstration of lineage-specific epitopes within TcII–VI has implications for sero-epidemiological studies of Chagas disease based on this antigen.

– comprise a large (>800) gene family (El-Sayed et al., 2005) believed to play a key role in host immune evasion and in maintaining infection (Buscaglia et al., 2006). The majority of mucin genes belong to the multi-gene sub-families TcMUC I and TcMUC II. Di Noia et al. (2002) assigned a bi-allelic single-copy gene to a third mucin family (TcMUC III), the two alleles of which were reported to correspond in distribution with lineages Tcl and TcII–VI, respectively. Antisera raised against a recombinant protein product of this gene from strain CL Brener (TcVI) identified the native form (TSSA). They also reported: (i) PvuII digestion of a TSSA PCR product occurred only for Tcl, not TcII–VI; (ii) the major antibody (Ab)-recognition epitope was restricted to a 10-amino acid region in TcII–VI (41-KPATGEAPSQ-50) where TcI versus TcII–VI differences clustered, with no immunological cross-reactivity between TSSA-I and TSSA-II isoforms. In a survey of chagasic patient sera from Argentina, Brazil and Chile, anti-TSSA antibodies were attributable only to the TcII–VI isoform, leading to the proposition that TcII–VI, not Tcl, is the cause of Chagas disease. However, the Di Noia et al. (2002) study was based on a genotypically narrow range of T. cruzi strains, including those grossly categorised as TcII–VI, and on sera from a limited geographical area, as was later acknowledged (Buscaglia et al., 2006). Furthermore, Tcl is known to cause severe and fatal Chagas disease with myocardiitis in Venezuela (Miles et al., 1981a; Ahé et al., 2004) and north-eastern Brazil (Teixeira et al., 2006).

Here, we determine the nucleotide (nt) and predicted amino acid sequence of a fragment of the TSSA gene across a panel of 25 T. cruzi strains representing a geographical and genotypic range that encompasses all described DTUs. A greater diversity is revealed than previously reported, including in the PvuII digest pattern, and in the region spanning the reported Ab-recognition epitope. The epitope considered specific for TcII–VI is shown to identify only Tcl, V and VI. In addition, the peptide described as Tcl-specific shares key features with TcIII and IV. We demonstrate that the bi-allelic description of the TSSA gene is not sufficient when all DTUs are examined, and that on the restricted basis of this gene, Tcl and IV share greater inferred phylogenetic affinities with TCI than with TcII, V and VI. The identification of lineage-specific epitopes within TcII–VI indicates a revised potential differential serology for epidemiological surveys of T. cruzi using this antigen.

2. Materials and methods

Table 1 lists the T. cruzi strains used in this study and their origins, all of which were biological clones. The PCR primers T5/ATG/E and EMT5/A, as described in Di Noia et al. (2002), were used to amplify an approximately 190 bp region of the TSSA gene from genomic DNA across the panel of strains listed in Table 1. Reactions comprised of 1× NH4 reaction buffer, 1.5 mM MgCl2 (Bioline, UK), 40 μM dNTPs (NEB, UK), 10 pmol of each primer and 1 U BioTaq DNA polymerase (Bioline). Amplification conditions were: one cycle at 94°C for 3 min; 25 cycles at 94°C for 30 s, 50°C for 30 s, 72°C for 30 s; and one cycle at 72°C for 10 min. PCR products were digested using 2 U PvuII (Promega, UK) and separated by electrophoresis on 2.5% agarose gels (Bioline). DNA sequencing was performed using the BigDye Terminator v3.1 RR-100 kit (Applied Biosystems, UK) according to standard protocols. Sequence alignment was achieved using BioEdit software (Hall, 1999), phylogenetic analysis using MEGA4 software (Tamura et al., 2007), and non-synonymous/synonymous nt substitutions per site ratios (dN/dS; ω) were calculated using SNAP software (Korber, 2000) employing the method of Nei and Gojobori (1986) with a Jukes-Cantor correction (http://hcv.lanl.gov/content/sequence/SNAP/SNAP.html).

3. Results

Table 1. For the hybrid strains from TcV and TcVI, certain nt peaks showed heterozygosity not recognised by the DNA sequencer basecaller software but observed on visual inspection of the electropherograms. These are represented by the data for the CL Brener strain (TcVI, Fig. 1B), and are depicted in the alignment by the degenerate symbols W (=A/T), K (=G/T) and R (=A/G). All sequences presented in Fig. 1A were derived in this study, and can be found in full under GenBank™ Accession Nos. GU059921–GU059937 and GU075671–GU075678; where sequences for certain strains had previously been submitted to GenBank™, these can be found with Accession Nos. AY367107–AY367113 and AF036443.

3.2. PvuII digest of TSSA PCR products

Sequencing of the TSSA PCR products revealed that the recognition site for PvuII (CAG; CTG, nts 125–130) is present in the...
sequences for TcI, III and IV but not TcII (CAGCTA). TcV and VI show heterozygosity at the 30 nt of the PvuII site (nt 130, Fig. 1B), leading to the predicted presence of both a functional and abolished restriction site in these strains. Di Noia et al. (2002) used PvuII digestion of the TSSA PCR products to discriminate TcI from TcII–VI, yielding 122 and 68 bp fragments for TcI, indicating that TcII–VI were not digested. However, our wider in silico analysis indicates that the TcIII and IV PCR products can also be digested by this enzyme, TcII cannot, and lineages TcV and VI would be predicted to show a hybrid digest pattern. To investigate this further, TSSA PCR products representative of the DTUs including hybrid strains were digested by PvuII, and the resulting samples run on a 2.5% agarose gel as shown in Fig. 2.

In confirmation of the in silico comparison, TcII was not digested whereas TcI, III and IV produced two fragments of predictable size. Digests from the hybrid lineages gave the undigested PCR product plus a faint 125 bp digest product (the 65 bp not being readily visualised on ethidium bromide-stained gels), reflecting the patterns of the TcII and III parents. Further confirmation of these digest patterns for reference strains is shown in Table 2.

### 3.3. Amino acid diversity in TSSA

Fig. 3 shows the predicted amino acid sequences encoded by the TSSA gene fragment across the DTUs, including the amino acid changes resulting from the nt polymorphisms in the TcV and VI strains. Several interesting features of the predicted amino acid sequences were observed. Firstly, using peptide scanning, the 10-amino acid region 41-KPATGEAPSQ-50 in TcII–VI was described as the Ab-recognition epitope that elicited the highest response with chagasic sera and allowed discrimination between TcI and TcII–VI (Di Noia et al., 2002). However, the amino acid sequences depicted in Fig. 3A reveal that this allele, although present in all TcII, V and VI strains examined here, is not found in either TcIII or IV. Second, in agreement with Di Noia et al. (2002), there is an absence of nt 106–108 in TcI compared with all of the TcII–VI strains (Fig. 1A), leading to an in-frame loss of residue Ser36 in the predicted amino acid sequence. This residue is part of the amino acid region identified in that publication as comprising a minor Ab-binding epitope. Thirdly, within the region encompassing residues 40–51, specific residues (Lys40Ala44Pro50Ser51) group TcI, III and IV whereas residues 39 and 42 split TcIII and IV. Last, for the hybrid strains TcV and VI the nt heterozygosity (shown in Fig. 1B) was predicted to result in amino acid changes in codons 20, 31 and 44.

### 3.4. Phylogenetic analysis based on TSSA sequences

Phylogenetic relationships of the TSSA nt sequences were analysed by reconstructing a Neighbour-Joining phylogeny based on p-distance (Fig. 4), taking into account the nt heterozygosity in the TcV and VI strains.

### 3.5. dN/ds ratio analysis of TSSA sequences

By comparing two DNA sequences and calculating the ratio of non-synonymous (changes amino acid, dN) and synonymous (does not change amino acid, dS) nt substitutions per site, a ratio of dN/dS greater than 1 can be used as an indicator that diversifying or positive selection has acted upon that sequence (Yang and Bielawski, 2000). Analysis of the TSSA sequences gave a dN/dS ratio $\omega = 1.233$.

### 4. Discussion

Understanding of the genetic diversity of T. cruzi has led to the description of intra-species lineages, or DTUs, and important in-
sights have been gained into their geographic range, mammalian hosts and natural transmission cycles (Miles et al., 2009). However, a key goal remains to clarify the relationship between parasite genotype and clinical symptoms.

In this study, we analysed a fragment of the TSSA gene previously reported to contain a TcII–VI-specific immunogenic region, across a panel of *T. cruzi* strains representing the genotypic and geographical range of DTUs. We found a greater diversity at both the nt and amino acid levels than had been described. The PvuII digestion patterns revealed here also identify differences within the TcII–VI DTUs. To date, TSSA has been reported as the only *T. cruzi* antigen that provides a serological marker to identify TcII–VI infection. However, we demonstrate that the described TSSA-II epitope is present in only TcII, V and VI, not in TcIII and IV, and overall TSSA is significantly more diverse in amino acid structure than previously described, particularly in the major Ab-recognition epitope (41-KPATGEAPSQ-50). The steric polymorphism suggested here may also have immunogenic implications in the mature glycoprotein. The presence of Ile31Ala44 in TcIII and IV in place of Ser31Thr44 in TcII (Fig. 3A) would prohibit O-glycosylation at these residues and thus alter mucin formation. This may also have relevance if mucins have immunomodulatory effects on the persistence of parasite infection (Buscaglia et al., 2006). Fig. 1B shows that the TcV and VI strains display allelic heterozygosity at these codons, in agreement with their origin as the result of a hybridisation process between TcI and III. This is also reflected by the Pvull digests of these strains, where the heterozygosity at nt 130 results in the presence of a hybrid TcII/III digest pattern.

The phylogenetic relationships depicted in Fig. 4 indicate affinities between TcI, III and IV, supporting the revised *T. cruzi* nomenclature (Zingales et al., 2009), which considers these DTUs independently, not as sub-groups within the previous TcIIa–e nomenclature. The dN/dS ratio for TSSA was >1, showing that TSSA heterogeneity, reflected at the amino acid level, is likely a result of significant positive selection pressure favouring diversification of the protein. By comparison, house-keeping genes under negative selection pressure typically have dN/dS ratios <1, for example, for *T. cruzi* glucose-6-phosphate isomerase (*GPI*) sequences (x = 0.112) (M. Lewis, unpublished data). This lends further support to the suggestion that the TSSA divergence has functional significance and that TSSA has an important role in the host–parasite relationship. Furthermore, when its mammalian-stage restricted expression is also considered, this indicates that vertebrate immune systems have probably been the source of selection pressure. A postulated role may be found in the process of host cell invasion by *T. cruzi*, which is a multi-step process involving interaction of numerous parasite and host cell-surface molecules. Steps include host intracellular Ca2+ accumulation, lysosome recruitment to the
cell surface and parasite internalisation (Andrews, 2002). As a bloodstream-stage expressed cell surface mucin, the diversity in TSSA could have implications for differential invasiveness between DTUs. The presence of distinct TSSA alleles in the genomes of TcV and VI strains may give them a putative selective advantage over non-hybrid strains. The well-characterised glycoproteins gp82 and gp85, both known to be involved with cell invasion (Yoshida, 2006), may also benefit from further study to evaluate the extent of stable polymorphism between lineages.

Work is now needed to examine whether the inter-DTU TSSA protein sequence variation described here can be exploited to discriminate further the DTUs in human infections, and enhance the understanding of the immunology and molecular epidemiology of the parasite across a wider geographical context. Di Noia et al. (2002) used a smaller set of T. cruzi strains than in this study, covering a narrower range of DTUs, and the chagasic sera used were from the southern cone countries only where TcII, V and VI are the DTUs most commonly found. We show here that the epitope previously identified as being characteristic of TcII–VI infection clearly only has the potential to detect serologically TcII, V and VI, so infection by TcIII or IV will be missed. Nonetheless, a serological test to distinguish TcII, V and VI from TcI, III and IV may still have utility. The genetic diversity and ecological niches of TcIII and IV are only recently beginning to be understood in sufficient detail. New hosts and a wider geographical distribution of TcIII have recently been reported (Llewellyn et al., 2009; Marcili et al., 2009a), while TcIV has been shown to be prevalent in several primate species and to be involved in oral transmission to humans in Amazonia (Marcili et al., 2009b).

A serological assay with the ability to discriminate immunodominant epitopes across the DTUs will allow identification of an individual's historic and extant lineage infections and aid investigation of clinical and epidemiological relationships. If appropriate successful tests can be devised, these may also be applicable to epidemiological tracking of the origins of infection in non-endemic areas caused as a result of transfusion, organ donation or vertical transmission routes. Screening of donor blood has begun recently in Europe (Gascon et al., in press) and the USA (www.cdc.gov/mmwr/preview/mmwrhtml/mm5607a2.htm).

This study demonstrates greater TcII–VI TSSA diversity than previously described in the nt sequence, PvuII-digest typing and amino acid diversity, crucially in the region described as the major Ab-binding epitope. By revealing the fuller extent of diversity and consequent implications for TSSA-based assays of T. cruzi infection,
a rationale is proposed for further immunological and molecular investigation of Chagas disease by the use of these lineage-specific epitopes for discriminatory serological assays.

Acknowledgements

This work was supported by the European Commission Framework Programme Project “Comparative epidemiology of genetic lineages of Trypanosoma cruzi” ChagasEpiNet, Contract No. 223034. We thank C. Barnabé (Institut de Recherche pour le Développement, Montpellier, France) for providing samples of T. cruzi genomic DNA.

References

**Key points, novel results and implications**

- The identification of a much greater diversity within the polymorphic region of the trypomastigote small surface antigen (TSSA) among *T. cruzi* lineages has been described in ANNEX 1 Bhattacharyya *et al.*, 2010.

- Here, synthetic lineage-specific epitope peptides based on this greater diversity were used in ELISA with sera from chagasic patients from throughout South America, in order to identify lineage-specific serological reactions.

- 79/113 (70%) of samples from Brazil, Bolivia, and Argentina recognised the TSSA epitope common to lineages TcII/TcV/TcVI, in agreement with previous descriptions of the distribution of these lineages. Comparison with clinical information showed that a higher proportion of Brazilian TSSApep-II/V/VI responders had ECG abnormalities than non-responders (38% vs 17%; p<0.0001).

- Among northern sera 4/20 (20%) from Ecuador reacted with TSSApep-II/V/VI. Also, 1/12 Venezuelan and 1/34 Colombian samples reacted with TSSApep-IV, in the first demonstration of a specific serological reaction against this lineage.

- In addition, a proposed TcI-specific epitope, described elsewhere (Mendes *et al.*, 2013), was demonstrated here to be highly conserved across lineages and therefore not applicable to lineage-specific serology.

- These results demonstrate the considerable potential for synthetic peptide serology to investigate the infection history of individuals, geographical and clinical associations of *T. cruzi* lineages

**Candidate’s contribution:**

The candidate performed and analysed all the ELISAs, designed the PCR primers and DNA analysis and alignment described in the submitted publication. The candidate prepared
the first draft of the manuscript, which was accepted for publication by *PLoS Negl Trop Dis* in April 2014 following academic peer review.
COVER SHEET FOR EACH ‘RESEARCH PAPER’ INCLUDED IN A RESEARCH THESIS

Please be aware that one cover sheet must be completed for each ‘Research Paper’ included in a thesis.

1. For a ‘research paper’ already published

1.1. Where was the work published? PLoS Neglected Tropical Diseases

1.2. When was the work published? 2014

1.2.1. If the work was published prior to registration for your research degree, give a brief rationale for its inclusion

1.3. Was the work subject to academic peer review? YES

1.4. Have you retained the copyright for the work? Yes / No

If yes, please attach evidence of retention.

If no, or if the work is being included in its published format, please attach evidence of permission from copyright holder (publisher or other author) to include work

2. For a ‘research paper’ prepared for publication but not yet published

2.1. Where is the work intended to be published?

2.2. Please list the paper’s authors in the intended authorship order

2.3. Stage of publication – Not yet submitted / Submitted / Undergoing revision from peer reviewers’ comments / In press

3. For multi-authored work, give full details of your role in the research included in the paper and in the preparation of the paper. (Attach a further sheet if necessary)

I PERFORMED AND ANALYZED ALL THE ELISA ASSAYS, DESIGNED THE PCR PRIMERS AND DNA ANALYSIS AND ALIGNMENT DESCRIBED IN THE PUBLICATION. I PREPARED THE FIRST DRAFT OF THE MANUSCRIPT.

NAME IN FULL (Block Capitals) TAPAN BHATTACHARYYA

send a brief article proposal (up to 150 words) to plosntds [at] plos.org.

2. Open Access

PLOS applies the Creative Commons Attribution (CC BY) license to all works we publish. Under the CC BY license, authors retain ownership of the copyright for their article, but authors allow anyone to download, reuse, reprint, modify, distribute, and/or copy articles in PLOS journals, so long as the original authors and source are cited. No permission is required from the authors or the publishers.

3. Publication Fees

To provide Open Access, PLOS uses a business model to offset expenses—including those of peer review management, journal production and online hosting and archiving—by charging a publication fee to the authors, institutions or funders for each article published.

Publication fees vary by journal and are payable for articles upon acceptance.

PLOS believes that lack of funds should not be a barrier to Open Access publication. Since its inception, PLOS has provided individual fee support and institutional fee support programs. The current offering includes:

**PLOS Global Participation Initiative (Low- and Middle-Income Country Assistance)**

Authors’ research which is funded primarily (50% or more of the work contained within the article) by an institution or organization from eligible low- and middle-income countries will receive partial (group 2 countries) or full (group 1 countries) fee funding paid by the PLOS Global Participation Initiative (GPI). Group 2 PLOS GPI country authors who need to request additional support should apply for PLOS Publication Fee Assistance instead of the PLOS GPI.

**PLOS Publication Fee Assistance (PFA)**

Publication Fee Assistance is intended for authors who demonstrate financial need. Information about an applicant’s application status for fee assistance will not be disclosed to journal editors or reviewers. PLOS publication decisions will continue to be based solely on editorial criteria.

**PLOS Institutional Fee Support Program**

PLOS currently offers an institutional program to support Open Access scientific publishing. Participating institutions have arrangements with PLOS to administer payment for full publication fees for their institutions’ authors. To be eligible, authors must be a corresponding author affiliated with the institution or agency in the Institutional Account Program (fully paid or restricted). *(Special note to UK authors — certain institutions will restrict payment to cover for Wellcome Trust and RCUK research grant recipients only.)* Authors who need to request additional support should apply for PLOS PFA.
Development of Peptide-Based Lineage-Specific Serology for Chronic Chagas Disease: Geographical and Clinical Distribution of Epitope Recognition

Abstract

Background: Chagas disease, caused by infection with the protozoan Trypanosoma cruzi, remains a serious public health issue in Latin America. Genetically diverse, the species is sub-divided into six lineages, known as TcI–TcVI, which have disparate geographical and ecological distributions. TcII, TcV, and TcVI are associated with severe human disease in the Southern Cone countries, whereas TcI is associated with cardiomyopathy north of the Amazon. T. cruzi persists as a chronic infection, with cardiac and/or gastrointestinal symptoms developing years or decades after initial infection. Identifying an individual’s history of T. cruzi lineage infection directly by genotyping of the parasite is complicated by the low parasitaemia and sequestration in the host tissues.

Methodology/Principal Findings: We have applied here serology against lineage-specific epitopes of the T. cruzi surface antigen TSSA, as an indirect approach to allow identification of infecting lineage. Chagasic sera from chronic patients from a range of endemic countries were tested by ELISA against synthetic peptides representing lineage-specific TSSA epitopes bound to avidin-coated ELISA plates via a biotin labelled polyethylene glycol-glycine spacer to increase rotation and ensure each amino acid side chain could freely interact with their antibodies. 79/113 (70%) of samples from Brazil, Bolivia, and Argentina recognised the TSSA epitope common to lineages TcII/TcV/TcVI. Comparison with clinical information showed that a higher proportion of Brazilian TSSApep-II/V/VI responders had ECG abnormalities than non-responders (38% vs 17%; p<0.0001). Among northern chagasic sera 4/20 (20%) from Ecuador reacted with this peptide; 1/12 Venezuelan and 1/34 Colombian samples reacted with TSSApep-IV. In addition, a proposed TcI-specific epitope, described elsewhere, was demonstrated here to be highly conserved across lineages and therefore not applicable to lineage-specific serology.

Conclusions/Significance: These results demonstrate the considerable potential for synthetic peptide serology to investigate the infection history of individuals, geographical and clinical associations of T. cruzi lineages.

Introduction

Chagas disease (South American trypanosomiasis) is still considered to be the most important parasitic disease in Latin America, despite notable success with control of household infestation by the triatomine insect vectors. Up to 8 million people are estimated to be chronically infected with the causative agent Trypanosoma cruzi, of whom at least 30% are likely to develop chagasic cardiomyopathy, in some cases with megasymphdromes of the intestinal tract [1,2]. Vector borne transmission is usually by
Author Summary

Chagas disease remains a significant public health issue in Latin America. Caused by the single-celled parasite Trypanosoma cruzi, the main route of infection is via contact with contaminated feces from blood-sucking triatomine bugs, but following successful insecticide spraying campaigns, congenital, food-borne, and transfusion/transplantation routes of infection have become more relevant. In the absence of successful chemotherapy, T. cruzi usually persists in the body for life, and in symptomatic cases may lead to death or debilitation by heart failure and/or gastrointestinal megasymphdromes. As a species, T. cruzi displays great genetic diversity, and is subdivided into lineages called TcI - TcVI. Associating T. cruzi lineage with clinical symptoms is a key goal of Chagas disease research. Direct isolation and typing of T. cruzi from chronically infected patients is hampered by the sequestration of the parasite in host tissues. Identifying lineage-specific antibodies in serum provides an alternative approach to determining an individual’s history of infection. Here, we performed lineage-specific serology using samples from a range of South American countries. We show that lineage-specific seropositivity is associated with geographical distributions and clinical outcome. These findings have wide implications for further diagnostics development and improved understanding of the epidemiology of Chagas disease.

contamination of mucous membranes or abraded skin with T. cruzi infected triatomine feces and sporadic oral outbreaks occur due to triatomine contamination of food [3]. Infection can also be propagated by congenital transmission and blood or organ donation, and this may arise among migrant populations far beyond the endemic regions in Latin America [4].

The species T. cruzi is remarkably diverse genetically and is currently described as comprising six distinct lineages or discrete typing units (DTUs, TcI-TcVI) [5]. The six lineages have complex disparate but partially overlapping geographical and ecological distributions and are circumstantially associated with different epidemiological features [6,7]. TcI is the principal agent North of the Amazon, in association with chagasic heart disease but where megasymphdromes are considered to be rare. TcII is one of three principal agents of Chagas disease in the Southern Cone region of South America, where chagasic cardiomyopathy, megaoesophagus and megacolon are found. TcIII is seldom isolated from humans but is widely distributed with the natural armadillo host Dasypus novemcinctus. TcIV is a sporadic secondary agent of Chagas disease in Venezuela [8]. TcV and TcVI, like TcII, are also agents of Chagas in the Southern Cone region, and are known to be relatively recent hybrids of TcII and TcIII [7,9].

Parasitological diagnosis in the acute phase of T. cruzi infection is by microscopy of fresh blood films, thin blood films, thick blood films or by haematocrit centrifugation and examination of theuffy coat, the latter being recommended particularly for congenital cases. In the chronic phase recovery of live organisms may be attempted by multiple blood cultures or xenodiagnosis with colony bred triatomine bugs with limited sensitivities, or parasite DNA may be detectable by amplification.

Serological diagnosis of T. cruzi infection is usually performed by either indirect immunofluorescence (IFAT) or indirect haemagglutination (IHA) or enzyme-linked immunosorbent assay (ELISA), giving >94% sensitivity and specificity [2]. There are several commercially available diagnostic kits, including rapid lateral flow tests but sensitivities may not be equivalent, particularly when they are used in regions where non-homologous genetic lineages of T. cruzi are prevalent [8–10]. These serological methods give no information on the genetic lineage or lineages that a patient carries, and are not designed for that purpose.

A key objective of Chagas research therefore remains to follow up in detail the circumstantial evidence of a relationship between infecting T. cruzi lineage and the clinical outcome [6,7,11]. However, such analysis is complex and vulnerable to multiple confounders, including diversity of host susceptibility. Even if T. cruzi isolates can be recovered from the infected blood by parasitological diagnosis or if DNA can be amplified from blood, genotyping methods [12,13] do not provide an entire profile of the infecting lineages in an individual patient, because distinct T. cruzi lineages may be sequestered in the tissues [14]. An approach to overcoming this limitation is to identify infecting T. cruzi lineage in a more indirect way. One strategy to achieve this is by serological detection of antibodies that are produced in response to lineage-specific antigens.

Di Noia et al [15] described the trypomastigote small surface antigen (TSSA), encoded by a member of the TAMAUCII mucin gene family, expressed on the mammalian bloodstream trypomastigote stage of the T. cruzi life cycle. The authors reported that TSSA is dimorphic in sequence, with TSSA-I being present in TcI, and TSSA-II found in TcII-TcVI. On the basis of this finding the authors pioneered lineage-specific serology for Chagas disease through application of a TSSA-II recombinant antigen to serology with patients from the Southern Cone region of South America. Chagasic patients were only TSSA-II seropositive, which led to the suggestion that TcII could be benign. However, this suggestion was in conflict with the geographical predominance of TcI North of the Amazon and the acute and chronic clinical presentations of known TcI infections [16,17]. In subsequent publications E. coli-produced recombinant TSSA proteins have been used more widely for serology with humans and animals [18–23].

We have previously analysed TSSA diversity among a panel of T. cruzi isolates representing a broad geographical and ecological range of lineages TcI-TcVI [24]. We found a greater lineage-specific diversity than had previously been described. Lineages TcI, TcII, TcV, and TcVI were shown to share a common TSSA sequence. However, in both the hybrid lineages TcV and TcVI we found that two TSSA alleles were present at an heterozygous locus with the polymorphic epitope: one haplotypic was shared with TcII and in the second haplotypic a Thr was replaced by Ala at position 44 of the protein. Lineage-specific TSSA sites were also found in TcIII and TcIV strains [24]. Cânepea et al [25] suggested a functional significance for this diversity in that the TcI/TcV/ TcVI form of TSSA, but not the TcI form, has the property of binding surface receptor(s) and inducing signalling pathways in host cells prior to parasite internalisation.

Recently, Mendes et al [26] used a bioinformatic analysis of the reference genome of the TcVI strain CL Brener [27] to identify candidate peptides for differential screening with sera from mice experimentally infected with single, known T. cruzi lineages. A resultant peptide, derived from a putative RNA-binding protein, was reported to be applicable for TcI serology [26].

Here, we have used our expanded knowledge of the range of TSSA diversity to design and synthesise lineage-specific peptides. We assess the capacity of these peptides to provide antigens for lineage-specific serology by ELISA and thus reveal which lineages have infected individual patients during their lifetime. Furthermore, we examine the geographical and clinical distribution of recognition of the synthetic peptide epitopes. In addition, we also investigate the diversity of the gene coding for the peptide described [26] as applicable for TcI-specific serology.
Materials and Methods

Ethics statement

Human sera were collected as part of routine diagnostic examination, with local institutional ethical approvals, and in accord with EC ethical standards established as part of the ChagasEpiNet international collaboration. All human sera were anonymised and coded by letters and numbers that did not reveal patient identities. Production of mouse sera adhered to the European 3Rs policy of Refinement, Reduction and Replacement (99/167/EG: Council decision of 25/1/99), took place in authorised animal facilities by licensed staff in agreement with the European Directive 86/609/EEC, and with review and approvals under UK Home office regulations [Animals (Scientific Procedures) Act 1986; project licence number 70/6997 to the London School of Hygiene and Tropical Medicine].

Mouse and human sera

Mouse sera were from mice previously inoculated intraperitoneally with 10^9 organisms from stationary phase cultures containing infective metacyclic trypomastigotes, of known biological clones of T. cruzi representing the lineages. Sera were separated from whole mouse blood by allowing clotting at room temperature, overnight storage at 4°C, centrifugation at 12000xg for 10 mins and removal of the supernatant serum. Serum samples were stored 1:1 with glycerol at -20°C.

Human sera were from chronic cases of Chagas disease, confirmed by a combination of parasitological and serological diagnosis. As shown in Table 1, 113 samples were from the Southern Cone countries, Brazil, Bolivia and Argentina, and 66 samples were from countries North of the Amazon, Colombia, Ecuador, Venezuela, where Tcl has been considered to predominate. Brazilian sera were from patients who had a positive parasitological diagnosis at the time of serum collection, together with a full clinical history, their geographical origin, age and sex. Institutes providing sera were: Hospital das Clinicas, Goiania, Brazil; Universidad Mayor de San Simon, Cochabamba, Bolivia; Universidad Nacional de Salta, Argentina; Universidad Central de Venezuela, Caracas, Venezuela; Universidad de los Andes, Bogotá, Colombia; Pontificia Universidad Catolica del Ecuador, Quito, Ecuador. Endemic healthy controls were from the Hospital das Clinicas, Goiania, Brazil, and additional controls were 17 sera from Colombia that were serologically negative to T. cruzi lysate.

Synthesis of lineage-specific peptides

The synthetic peptides were prepared with an amino terminal tert-butyl molecule linked via a polyethylene glycol-glycine spacer so that they could be bound to avidin-coated ELISA plates. Importantly, this method increased their rotation and ensured that each amino acid side chain would be unavailable, as discussed previously [28].

Design of the peptides was based on the T. cruzi TSSA lineage-specific amino acid sequences previously described [24]; chimeric peptides comprised by TSSA-I and TSSA-II sequences were also designed and synthesised (Results; Figure 1). Synthetic peptides were prepared at the 20 μM scale on 100–200 mesh-size Finoc-Cys(Trt) Wang resin (0.5 mmol/g) (856006: Novabiochem, UK) using a Zinsser Analytic SMPS 350 (Zinsser Analytic, UK) or Advanced Chemtech Apex 396 (Advanced Chemtech, USA) robotic multiple peptide synthesizer. Aspartamide formation of aspartic acid residues was reduced by the use of OMe-protected Finoc-Asp(OMe)-OH (852104: Novabiochem, UK).

The coupling steps were performed using 0.5 M Fmoc-protected amino acids diluted in 6.76% (wt/vol) 1-hydroxybenzotriazole (HOBr)/dimethylformamide (DMF) (Activotec, UK/Rathburn Chemicals Ltd., UK) activated using 0.5 M N,N,N’,N’-tetramethyl-O-(1H-benzotriazol-1-yl)uronium hexafluorophosphate (HBTU) (851006: Novabiochem, UK) with 1M N,N-disopropylethylamine (DIPEA) (Rathburn Chemicals Ltd., UK), while the deprotection steps were performed using 20% (vol/vol) piperdine/DMF (Rathburn Chemicals Ltd., UK). The carboxyl- and amino- regions flanking the core epitope sequences contained additional glycine (G) residues to increase rotation (high dihedral角度) of their carboxyl-terminal cysteine (C) residue and their amino-terminal spacer and molecular label. Their amino termini were labelled via a polyethylene glycol (PEG) spacer (Fig 1A) through sequential couplings with 0.5 M Fmoc-NH-(PEG)3-COOH (13 atoms or 20 atoms) (851034 or 851031: Novabiochem, UK) followed by 0.5 M biotin (B4501: Sigma Aldrich, UK) using the more efficient coupling agent, 0.5 M N,N,N’,N’-tetramethyl-O-(7-azabenzotriazol-1-yl)uranylnium hexafluorophosphate (HATU) (851013: Novabiochem, UK) containing 1 M DIPEA. The final peptides were each washed 5 times with dichloromethane and then methanol (Rathburn Chemicals Ltd., UK) before being dried in a freeze-drier (Edwards, UK). Peptide cleavage was performed by reaction for 3–4 hours using 1% (wt/vol) phenol, 2% H2O, 2.5% (vol/vol) trisopropyl silane (233781: Sigma Aldrich, UK) and 2% (vol/vol) 2,2’-ethylenedioxoydiethanol (3,6-dioxa-1,8-octanediol) (DODT) (465178: Sigma Aldrich, UK) in trifluoroacetic acid (Rathburn Chemicals Ltd., UK) [29]. The cleaved peptides were then precipitated in cold (0°C) peroxide-free diethyl ether (Rathburn Chemicals Ltd., UK), centrifuged at 2,000xg; the supernatants were discarded and the precipitation and centrifugation steps were repeated twice. The peptides were then dried under a stream of anhydrous argon gas (BOC, UK) before being stored at -80°C.

For purification each peptide was subsequently dissolved in 500 μl of 2,2,2, trifluoroethanol (T63002: Sigma Aldrich, USA), made to 5.5 ml with 5% (vol/vol) fur UV grade acetonitrile (Rathburn Chemicals Ltd., UK) in H2O containing 0.1% (vol/vol) trifluoroacetic acid, and then subjected to reversed-phase HPLC using a 5 ml injection loop, a 5-95% acetonitrile gradient run at 9 ml/min over 30 min through an ACE C18 300 Å 250×2.1 mm preparative column (ACE-231-2520: Advanced Chromatography Technologies, UK) in a Beckman Gold preparative HPLC system (Beckman, USA). The main peaks, detected at a wavelength of 215 nm, were collected and freeze-dried before storage at -80°C.

Additionally, peptides TSSApep-I/V/VI and MenTCI were also synthesised commercially (Genosphere Biotechnologies, Paris, France).

Purified peptides were prepared as 1 mg/ml stock solutions in PBS and the addition of biotin in the last coupling was assessed by ELISA. For this assay, 10 μg/ml of each peptide was prepared in 1x carbonate-bicarbonate coating buffer (15 mM Na2CO3, 34 mM NaHCO3, pH 9.6) and added at 50 μl/well to 96-well ELISA plates (733–0465: Immulon 4HBX, VWR, UK). Plates were coated with an adhesive sheet and incubated overnight at 4°C. Following three washes with PBS containing 0.05% (vol/vol) Tween 20 (P7949: Sigma Aldrich, UK) (PBS/T), 200 μl/well blocking buffer (PBS/2% skimmed milk powder (Premier International Foods, Spalding, UK) was added and incubated at 37°C for 2 hrs. Following three washes, a 1:2000 dilution of peroxidase-labeled streptavidin (S2438: Sigma Aldrich, UK) in PBS/T containing 2% skimmed milk powder (PBS/T/M) was added at 50 μl/well, and incubated at 37°C for 1 hour. After washing six

times with PBS/T, 50 mM phosphate/citrate buffer (pH 5.0) containing 2 mM o-phenylenediamine HCl (P1526; Sigma Aldrich, UK) and 0.005% (vol/vol) H2O2 (216763: Sigma Aldrich, UK) was added at 50 µl/well and the absorbance values were determined at a wavelength of 490 nm (MRX, Dynatech, USA).

Production of whole-cell lysate antigen

*T. cruzi* was cultured as previously described [30]. For production of lysate antigen, mid-to-late log phase cultures of a TcII strain (IINF/PY/00/Chaco23cl4) of *T. cruzi* were centrifuged at 800 × g for 10 mins at 4 °C in an Allegra X-15R benchtop centrifuge (Beckman Coulter, UK). After washing in PBS, cell pellets were subjected to 3 cycles of flash-freezing in liquid nitrogen and thawing in a cold water bath. Cell lysates were then sonicated for 30 sec, with intervals on ice, using a Soniprep 150 sonicator (MSE), at 12 µm amplitude. Sonicated lysates were centrifuged at 13000 rpm for 1 min, and the supernatant used as antigen in ELISA. Protein concentration was determined using the BCA Protein Assay kit (PN23227: Fisher Scientific, UK).

Lineage-specific peptide ELISA

Immulon 4HBX 96-well flat bottomed ELISA plates were coated with 1 µg/100 µl/well of avidin (A9275; Sigma, UK) diluted in 1× carbonate-bicarbonate coating buffer for binding to lineage-specific peptide, and in separate wells coating was with TcII *T. cruzi* lysate at 0.2 µg/100 µl/well to act as a serologically positive control for each sample. Plates were covered an adhesive sheet and incubated overnight at 4 °C. The following day, unbound avidin and lysate were removed, the plate washed three times with wash buffer PBS/T, then wells were blocked with 200 µl blocking buffer PBS/T/M at 37 °C for 2 hrs. Following three washes, 1 µg/100 µl/well TSSA lineage-specific peptide in PBS/T/M was incubated with the avidin-coated wells at 37 °C for 1 hr. Following three washes, 100 µl/well of donkey anti-human IgG (H+L)-HRP (709-035–149; Jackson Immunoresearch, Pennsylvania, USA), diluted 1:5,000 in PBS/T/M was added, and incubated at 37 °C for 1 hr. Following six washes, plates were developed and read as described above, except that the volumes were 100 µl for substrate and 50 µl for 2M H2SO4. Replica plates were run in duplicate simultaneously.

Statistical analysis

Cut-off values for ELISAs with human sera and peptides were calculated from the mean plus 3 standard deviations compared to the endemic healthy controls from Goiânia, Brazil. Statistical analysis (2-tailed unpaired t-test) on the Brazilian TSSApep-II/V VI seropositives and non-responders was performed using GraphPad Prism version 4.02 for Windows (GraphPad Software, San Diego, California, USA).

Analysing diversity of the putative TcI epitope

We designed PCR primers MenTcI FOR (5′ ATGCCA-CAATCGAAACCAAG 3′) and MenTcI REV (5′ TCACAA-CAAACGTTTGGCTG 3′) (synthesised by Eurofins MWG Operon, Germany) to amplify the whole open reading frame (ORF) of the putative RNA–binding protein (Tc00.1047053511837.129) which was described as containing an epitope and corresponding peptide applicable for TcI serology [26]. *T. cruzi* strains, from which genomic DNA was used as amplification template, are listed in Table 2. Amplification reactions were performed in a total volume of 20 µl, and comprised of 1×NH4 reaction buffer supplemented with 1.5 mM MgCl2 (Bioline, UK), 200 mM dNTPs (New England Biolabs, UK), 10 pmol of each primer, and 1 U BioTaq DNA polymerase (Bioline). Amplification conditions were: 1 cycle of 94 °C, 3 mins; 25 cycles of 94 °C for 30 secs, 55 °C for 30 secs, 72 °C for 30 secs; 1 cycle of 72 °C for 10 mins. Five microliters of the PCR reaction were analysed by electrophoresis on 1.5% agarose gels (Bioline); amplification products were purified from the remaining reaction by precipitation with an equal volume of isopropanol at room temperature, followed by washing with 70% EtOH, air-drying and resuspension in ddH2O. Bi-directional DNA sequencing, using each PCR primer separately at 3.2 pmol, was achieved using a BigDye

Linear B-epitope profiling

Computer analysis of the TSSA-I and the TSSA-II/V/VI common epitope was performed using EpistD2-B software (v 2.1.17, Matrix B7.1) from Aptum Biologics Ltd (Southampton, Hampshire, UK). The algorithm of the program allows prediction of potential linear B-epitopes and their immunogenicity. The data were used in graphical format.

Accession numbers

Nucleotide sequences derived in this manuscript are available under GenBank accession numbers KJ395471 - KJ395495.

Results

TSSA provides potential epitopes specific for each *T. cruzi* lineage

The structures and sequences of the peptides synthesised, indicating the lineage-specific amino acids, are shown in Figure 1, as based on the comparisons of diversity previously described [24]. In addition to the peptides representing single lineages we synthesised two chimeric peptides, one with TSSA-I residues at the N terminus and TSSA-II residues at the C terminus, and the second with TSSA-II at the N terminus and TSSA-I at the C terminus (Figure 1B).

Consistent with the known extensive genomic divergence between TcI and TcII, eight residues differed between their TSSA potential epitopes. Five and six residues separated TSSA-II from TSSA-III and TSSA-IV, respectively. Four residues distinguished TSSA-I from TSSA-III and two residues separated TSSA-I from TSSA-IV, in accord with their somewhat greater affinity with TcI. A single residue differed between the TSSA-II haplotype shared by TcII, TcV and TcVI and the second haplotype present at the heterozygous locus in the hybrids TcV and TcVI.

Synthetic peptides are recognised by serum antibodies

Sera from mice experimentally infected with biological clones of TcII, TcV and TcVI strains recognised TSSApep-II/V/VI in serology by ELISA, and sera from TcIII and TcIV murine infections reacted with the corresponding TSSA peptides (Bhat-tacharyya et al, in preparation), encouraging the evaluation described here of the diagnostic potential of all the synthetic peptides with sera from patients with chronic Chagas disease.

Figure 2 shows examples of ELISA plates with *T. cruzi* lysate and lineage-specific synthetic peptides as antigens. Sera from normal healthy endemic controls did not react with the *T. cruzi* lysate or with any of the synthetic peptides. Without exception all
sera from patients with chronic Chagas disease recognised the *T. cruzi* TcII lysate antigen preparation. Figure 2 also provides examples of sera from Brazil, Argentina and Ecuador that recognised TSSApep-II/V/VI, indicative of infection with TcII, TcV or TcVI. A positive result for the epitope derived from the TcV/VI specific haplotype indicates definite infection with TcV or TcVI. Some of these sera (e.g. B6 & B10) reacted with both TSSApep-II/V/VI and TSSApep-V/VI representing the haplotype restricted to TcV and TcVI, indicating infection with a hybrid strain, possibly in conjunction with a TcII infection. Recognition of the TcV and TcVI restricted epitope was never seen in the absence of recognition of the TSSApep-II/V/VI.

A Venezuelan serum (V4 in Figure 2) recognised TSSApep-IV, consistent with the known presence of TcIV as a secondary agent of Chagas disease in Venezuela [16]. However, this serum also bound to TSSApep-III, which only differs by 2 of 16 residues.

An antibody response to TSSApep-I was exceptional, only two sera were reactive from the entire set of samples (Table 1) of which one weak reactor (Argentina A3) is shown in Figure 2.

Chimera TSSApep-I/-II and chimera TSSApep-II/-I were designed to determine whether the antigenic epitope resided at the N or C terminus of the peptides. Chimera TSSApep-II/-I was recognised by 71/83 TSSApep-II/V/VI reactive sera, as demonstrated for example by Argentine patients A1, A2 and A4 (Figure 2). In comparison, only 11/83 recognised the chimera TSSApep-I/-II, indicative that, although not precisely mapped, the dominant region of the epitope lies towards the N terminus of the peptide and that in some patients the N terminus is adequate to provide a detectable epitope. A single TSSApep-IV/TSSApep-III positive serum also recognised the chimera TSSApep-I/-II peptide.

Four of 186 samples responded to all wells containing peptides; these were demonstrated to bind non-specifically to avidin in the absence of peptide, but not to cross react with milk proteins (data not shown).

**Rare recognition of the TSSA-II/V/VI common peptide in northern South America**

The 186 sera from patients with chronic Chagas disease spanned a geographical range from Argentina to Venezuela. Three Southern Cone countries were included, where TcII, TcV and TcVI have been reported to be endemic, and three countries from northern South America, where TcI is considered to predominate. A summary of the geographical distribution of the antibody responses to all the lineage-specific synthetic peptides is shown in Table 1. Of the sera recognizing TSSApep-II/V/VI, 79 out of 83 were from the Southern Cone countries and four were from Ecuador. Of these 83 sera, 13 sera also recognised TSSApep-V/VI, 12 from Southern Cone countries and one of the four sera from Ecuador, indicating presence of TcV or TcVI, possibly with TcII co-infection. Independently of the lineage-specific peptides, we also examined the response to two different chimera peptides, each comprising different combinations of sequences from TSSApep-I and TSSApep-II/V/VI. Of the Bolivian, Ecuadorian and Argentine sera which reacted with TSSApep-II/V/VI, all reacted with chimera TSSApep-II/-I, but only two samples (Ecuadorian) also reacted with chimera TSSApep-I/-II. In the case of Brazilian samples, of the 67 that reacted with TSSApep-II/V/VI, 55 reacted with chimera TSSApep-II/-I, and of these 55, 9 also reacted with chimera TSSApep-I/-II. Only one sample (Venezuelan) reacted with chimera TSSApep-I/-II but not with TSSApep-II/V/VI or chimera TSSApep-II/-I. TSSApep-I failed to detect antibodies, regardless of origin of the chagasic sera, with the exception of two sera, one each from Brazil and Argentina. Four sera recognised both TSSApep-IV and TSSApep-III, consistent with cross-reaction due to the close similarity between these epitopes.

The country by country distribution of antibody recognition of the peptides is given in Table 1. ELISA cut-offs and absorbance values for each lineage-specific peptide are shown in Figure 3. Each data point represents the mean A490 readout of duplicate assays of the serum sample with the lineage specific peptide. In Figure 3, the samples giving the highest reading for TSSApep-III from Colombia and Venezuela are the same samples that recognised TSSApep-IV.

**Antibodies to the TcI/TcV/TcVI peptide are more frequent among symptomatic Brazilian patients**

60/63 of the Brazilian patients with chronic Chagas disease who were seropositive against TSSApep-II/V/VI had detailed clinical evaluation, and of these 60 patients, 23 (38%) had ECG abnormalities typical of Chagas disease. 23/28 patients seroreactive for TSSApep-II/V/VI also had detailed clinical evaluation, but in contrast only 4 of these latter, different 23 patients had such ECG abnormalities (p<0.0001).

**Novel bioinformatic algorithms predict highly antigenic residues**

The sequences coding for the TSSA proteins containing the TSSApep-I and TSSApep-II/V/VI epitopes were subjected to a
novel bioinformatic analysis using EpiQuest-B program that builds the immunogenicity profile for linear protein sequences and predicts the location and potential immunogenicity of the linear B-cell epitopes (Litvinov et al, in preparation) in order to give an antigenicity score for the polymorphic region. The algorithm predicted high scores within the TSSApep-II/V/VI epitope region, but much lower for TSSApep-I, as shown in Figure 4.

The different antigenicity scores indicate that the N-terminal TEN in TSSApep-II/V/VI is the dominant epitope, explaining the frequent recognition of chimera TSSApep-II/-I (Figure 1) despite the higher scoring C-terminal GEAPS, which provides a secondary site of recognition for some (Brazilian) sera that respond to TSSApep-I/-II (Figure 1). Neither the TEN nor GEAPS is present in TSSApep-I, explaining the rare recognition of this epitope. The GEAPS, which is also present in TSSApep-III and TSSApep-IV, gave much lower antigenicity scores in these peptides, in the absence of the upstream TEN in these sequences (data not shown).

Comparative diversity of the putative TcI-applicable peptide reveals high conservation across lineages

Mendes et al [26] used heterozygous loci in the CL Brener genome to identify candidate lineage-specific epitopes. One conserved and three potentially lineage-specific peptides were synthesised, described as deriving from hypothetical protein Tc00.1047053510421.310 (conserved epitope peptide), putative RNA-binding protein Tc00.1047053511837.129 (for TcI serology), putative ADP-ribosylation factor GTPase activating protein Tc00.1047053511589.70 (for TcII), and putative DNA-directed RNA polymerase III subunit Tc00.1047053510359.320 (for TcVI) that displayed some discriminatory power in ELISAs and affinity-ELISAs based on differential range of absorbance values. The putative TcI epitope was described as restricted to TcI and TcVI and applicable to serological identification of a specific response to TcI. We examined the diversity in the coding sequence for this epitope, using a panel of T. cruzi strains across the lineages (Table 2). A single amplicon of 381bp was produced by PCR from all strains using primers MenTcI FOR and MenTcI REV. Examples from TcI and TcII strains are shown in Figure 5.

However, in comparative sequencing across isolates representing the lineages we found this epitope to be highly conserved (Table 2). This epitope had the same amino acid sequence across all the strains and lineages analysed here with the exception of strains Y and CBB (TcII) and Para 6 (TcV). In strains Y and CBB, a heterozygous nucleotide (G/C) residue led to the presence of two predicted amino acids, Ser or Thr.

The region homologous to the reported TcI-applicable epitope, which was described as specific to a TcII strain, but given only as amino acid sequence [26], was subject to BLAST against NCBI and TriTrypDB databases. There were very low stringency homologies returned by TriTryp BLAST to various T. cruzi proteins (mainly around the PPP tripeptide), none of which was described as RNA-binding proteins. On NCBI BLAST, highest-scoring matches were to various bacteria and fungi, none to trypanosomes. Furthermore, none of 55 sera from northern countries of South America, where TcI is highly endemic, bound to the TcI synthetic peptide reported in Mendes et al in our ELISA assays (data not shown).

Discussion

Kong et al [32] developed lineage-specific serology for the protozoan parasite Toxoplasma gondii, which is difficult to isolate from chronically infected patients, and most isolates of which are classified into clonal lineages type I, II, or III. Serology with synthetic peptides based on diversity within the dense granule proteins GRA6 and GRA7 was able to distinguish type II from non-type II infections in humans. Using discriminatory serology, it was possible to demonstrate that the T. gondii lineages had different

![Figure 3. Recognition of TSSA lineage-specific peptides shows a disparate geographical distribution.](image-url)
continental distributions [33], and that adult offspring of type I-infected mothers had a significantly increased risk for the development of psychoses [34].

Here we have used detailed comparative analysis of the genetic diversity of the T. cruzi TSSA gene encoding the protein core of the mucin TSSA, to design synthetic peptides for lineage-specific serology of T. cruzi infection history. These epitopes were presented on an avidin-coated solid phase via an amino terminal biotin-label linked to a polyethylene glycol-glycine spacer to increase rotation and ensure that each amino acid side chain could freely interact with antibodies. We synthesised and tested these lineage-specific peptides in ELISA with 186 human sera from six countries, three in the Southern Cone region of South America and three in northern South America. We have selected these countries because typing of T. cruzi isolates with multilocus enzyme electrophoresis (MLEE) [6], multilocus sequence typing (MLST) [35] and multilocus microsatellite typing (MLMT) [17] has repeatedly indicated the predominance of TcII, TcV and TcVI as the agents of Chagas disease in Southern Cone countries yet the contrasting high prevalence of TcI in patients North of the Amazon [7,11]. Nevertheless, there have been some reports that TcII, as identified by genotyping, can be found among isolates from humans and domestic triatomine bugs in northern endemic regions, for example in Colombia and Guatemala [36–38].

Lineage-specific serology is therefore of special interest for T. cruzi, because of the disparate geographical distributions of both the T. cruzi lineages and clinical manifestations of chronic Chagas disease. Thus as long ago as 1981, Miles et al proposed that the presence of chagasic cardiomyopathy with megaoesophagus and megacolon in Southern Cone countries, yet absent prevalence of associated megasymphdromes from Venezuela, may be related to the comparative predominance of TcI as the agent of Chagas disease in northern South America [6]. Nevertheless the evidence of a link between infecting lineage of T. cruzi and prognosis of chronic Chagas disease remains circumstantial. As with T. gondii, this is partly due to the difficulty of isolating and genotyping T. cruzi from chronic chagasic patients. Blood culture and xenodiagnosis have limited sensitivity and may be selective for faster growing biological clones. Furthermore, even if parasites or DNA can be recovered from chronically infected patients, the resultant T. cruzi isolates may not be representative of the genetic diversity in the patient, because T. cruzi replicates intracellularly and lineage genotypes may be sequestered in the tissues but not recoverable from the circulating blood [14]. Serology with lineage-specific antigens provides a means of profiling an individual’s history of T. cruzi infection, to overcome inaccessibility of the parasite to direct genotyping during chronic infections.

TSSA provides a good candidate for development of synthetic peptide-based, lineage-specific serology, because no TSSA homologue beyond the species T. cruzi has been detected by genomic comparisons, and a lineage-specific candidate epitope can be represented by a single synthetic peptide. Thus such peptides are unlikely to generate false positive ELISA results with sera from healthy controls or from patients with other infectious or autoimmune diseases. In the multiple ELISAs performed here none of the healthy controls recognised any of the synthetic peptides, and all were also serologically negative with the T. cruzi lysate (Figure 2). However, sera from four of the chagasic patients bound non-specifically to plates coated with avidin alone and thus

**Figure 4.** Computer-predicted antigenicity score is much higher for TSSA-II/V/VI sequence than TSSA-I. Polymorphic sequences of [A] TSSA-I and [B] TSSA-II/V/VI showing regions of high antigenicity in red, and low antigenicity in blue. A few amino acid replacements in TSSA-I lead to disappearance of the immunogenic epitope that is present in TSSA-II/V/VI sequence. doi:10.1371/journal.pntd.0002892.g004

**Figure 5.** PCR amplification of the ORF containing the reported TcI-applicable epitope. Only the amplicon of predicted size (381 bp) was amplified by the reaction conditions. –ve = no template DNA control. Mk = Hyperladder IV (Bioline, UK). doi:10.1371/journal.pntd.0002892.g005
spuriously appeared to recognise all peptides; such artificial binding to avidin has been observed in other serological studies [39].

Since the initial report of the sequence and antigenic dimorphism of TSSA by Di Noia et al [15], E. coli-produced recombinant TSSA proteins have been used as antigen with human and animal sera, as summarised in Table 3. Recognition of only TSSA-II by chronic chagasic sera from the Southern Cone region was initially interpreted as suggesting that only TcII caused chronic Chagas disease [15]. However there are many descriptions of Chagas disease and chronic cardiomyopathy in TcI endemic regions. Recognition of recombinant TSSA-I by human chagasic sera has been reported by western blot but not by ELISA [18,21]. One western blot study with recombinant TSSA-II and TSSA-I has recorded an unexpected level of TcII in northern South America and Mexico [21]. The recombinant TSSA proteins used as antigens as described encompass up to 26 amino acids flanking the polymorphic region [15,20,21], which are highly conserved between TSSA-I and TSSA-II.

The lineage-specific peptide representing the epitope common to TcII/TcV/TcVI was recognized by a large number of sera (Figure 2, Table 3). Four sera also recognised TSSApep-III, which shares 14 of 16 key amino acids with TcII/TcV/TcVI in those Colombian patients.

Apart from one Argentine and one Brazilian serum, no clear specific reaction with TSSApep-I was observed, even with sera from known TcI endemic regions in Venezuela, Colombia and Ecuador. The few TSSApep-I/V/VI seropositive samples from Brazil that also reacted with chimera TSSApep-I/-II did not react with TSSApep-I. One possibility is that the TSSA-I protein, if expressed at all in chagasic patients, is not sufficiently immunogenic to generate an antibody response, possibly due to post-translational glycosylation of the core peptide sequence. Identification of the disaccharide Galα1,3Galβ as the immunodominant glycopeptide present in the O-linked mucins, i.e., those glycosylated on serine or threonine residues of the peptide chain, has been reported recently [44,45], and both serine and threonine are represented by one additional residue in TSSApep-I as compared to the known high prevalence of these lineages in those countries [23]. All sera from Bolivia, Argentina and Ecuador, and the great majority of those from Brazil, that recognised TSSApep-II/V/VI also reacted with chimera TSSApep-II/-I indicating that crucial residues reside in the N-terminal part of the TSSA-II/V/VI epitope.

We found that few serum samples from the three countries in northern South America recognized TSSApep-II/V/VI or TSSApep-V/VI. This is consistent with the literature on the geographical distribution of T. cruzi lineages based on genotyping of isolates from domestic and sylvatic transmission cycles. In fact only 4 sera from Ecuador were seropositive with TSSApep-II/V/VI out of 66 from these northern countries. At least 3 of these 4 Ecuadorian serum samples originated from the Loja region in southern Ecuador, where TcI has been isolated [43], close to the border with Peru. Risso et al [21] reported the identification of TcII in Colombia, Venezuela, and Mexico using western blots with TSSA-I recombinant antigen. However, when the same Colombian sera samples were tested here using the lineage-specific peptides we found no TSSApep-II/V/VI seropositive patients.

Thus with our data we are unable to confirm the presence of TcII/TcV/TcVI in those Colombian patients.

Only four sera, including one from Venezuela where TcIV is known to sporadically infect humans, recognised TSSApep-IV. All four sera also recognised TSSApep-III, which shares 14 of 16 residues, presumably due to cross reaction, as we have observed with experimental murine sera (Bhattacharyya et al, in preparation).

Apart from one Argentine and one Brazilian serum, no clear specific reaction with TSSApep-I was observed, even with sera from known TcI endemic regions in Venezuela, Colombia and Ecuador. The few TSSApep-I/V/VI seropositive samples from Brazil that also reacted with chimera TSSApep-I/-II did not react with TSSApep-I. One possibility is that the TSSA-I protein, if expressed at all in chagasic patients, is not sufficiently immunogenic to generate an antibody response, possibly due to post-translational glycosylation of the core peptide sequence. Identification of the disaccharide Galα1,3Galβ as the immunodominant glycopeptide present in the O-linked mucins, i.e., those glycosylated on serine or threonine residues of the peptide chain, has been reported recently [44,45], and both serine and threonine are represented by one additional residue in TSSApep-I as compared

*Chemiluminescent ELISA; †called by authors TSSA VI, but the same as that first described as TSSA-II. doi:10.1371/journal.pntd.0002892.t003
with the TSSA-II epitope. However, equally likely, the TSSA I epitope may be conformational, with a structure that is not represented by the linear peptide. Also, alternative immunodominant epitopes elsewhere in TSSA-I may skew the humoral response away from the sequence represented by TSSApep-I.

We were interested to see whether there was a difference in the proportions of TSSApep-II/V/VI seropositive and seronegative patients presenting with clinical symptoms of chronic Chagas disease. Remarkably, there was a clear statistically significant difference: 23/60 (38%) of the Brazilian TSSApep-II/V/VI seropositives had ECG abnormalities typical of Chagas disease, whereas such abnormalities only occurred in 4/25 (17%) of the seronegatives (p<0.0001). One possible interpretation of these data is that TSSApep-II/V/VI seronegative patients may not be infected with these lineages but with some less pathogenic strains. Alternatively, such seronegative patients may be infected with TcII, TcVe or TcVI but the absence of an immune response to the TSSA-II/V/VI common epitope may be an indicator of a long term better prognosis; however confirmation would require a more extensive and longitudinal study. However, the frequencies of megaesophagus (43% vs 48%) and megacolon (10% vs 8.7%) were not significantly different between the TSSApep-II/V/VI seropositive and seronegative groups respectively.

*Trypanosoma rangeli* is non-pathogenic to humans, is found sympatric with *T. cruzi*, particularly in northern South America, and serological cross-reaction between these species has been recognised [46]. The divergence of the TSSA epitopes in *T. cruzi* and the lack of response to the peptides with sera from northern South America, indicate that monospecific sera from patients infected with *T. rangeli* alone will not recognise these synthetic peptide epitopes.

**References**

A recent paper reported the identification of a TcI epitope for lineage-specific serology [26]. However, upon analysing the sequence diversity in the ORF coding for the parent protein across *T. cruzi* lineages, in contrast we found a very high degree of sequence conservation across the lineages. Thus, we were not able to confirm any Tc-specific epitope. In silico

PUBLICATIONS ARISING: Leishmania donovani complex and visceral leishmaniasis

Key points, novel results and implications

- In cases of suspected visceral leishmaniasis, the rapid diagnostic test (RDT) for the presence of anti-Leishmania antibodies is based on the antigen rK39, a fragment of a kinesin-like protein comprising 39 amino acid repeats, originally cloned from a Brazilian L. infantum (syn. L. chagasi) strain. However recent multi-centre trials have shown much lower sensitivities in East Africa than the South Asia, for unclear reasons.

- Here, the molecular diversity of the rK39 homologous sequences among East African L. donovani strains was investigated as a possible factor for this differential sensitivity. Diversity of HASPB1 and HASPB2 gene repeat sequences, used to flank sequences of a kinesin homologue in the synthetic antigen rK28 designed to reduce variable RDT performance, was also investigated.

- Coding sequences of rK39 homologues from East African L. donovani strains were amplified from genomic DNA, analysed for diversity from the rK39 sequence, and compared to South Asian sequences. East African sequences were revealed to display significant diversity from rK39. Most coding changes in the 5’ half of repeats were non-conservative, with multiple substitutions involving charge changes, whereas amino acid substitutions in the 3’ half of repeats were conservative. Specific polymorphisms were found between South Asian and East African strains.

- Non-canonical combination repeat arrangements were revealed for HASPB1 and HASPB2 gene products in strains producing unpredicted size amplicons.

- This work demonstrates that there is extensive kinesin and HASPB genetic diversity among strains in East Africa and between East Africa and South Asia, with ample scope for influencing performance of diagnostic assays based on these antigens.

Candidate’s contribution:
The candidate designed all the PCR primers used in this publication, following an exhaustive search of the relevant literature and databases. The candidate performed most of the cell culture, and all the DNA extractions, PCRs, gel electrophoresis, DNA sequencing preparation, alignment and analysis of the kinesin and HASPB genes as described in this publication. The candidate prepared the first draft of the manuscript, which was accepted for publication by *PLoS Negl Trop Dis* in December 2012 following academic peer review.

(Double-click on image to view embedded document)

As another possible explanation of the reported differential sensitivity of the rK39 RDT in East Africa and South Asia, the anti-*Leishmania* IgG levels of VL patients from endemic regions of Sudan and India were directly compared in ELISA against *Leishmania* lystaes originating from both regions. That work is described in the following section (ANNEX 4 Bhattacharyya *et al.*, 2014).
COVER SHEET FOR EACH ‘RESEARCH PAPER’ INCLUDED IN A RESEARCH THESIS

Please be aware that one cover sheet must be completed for each ‘Research Paper’ included in a thesis.

1. For a ‘research paper’ already published

send a brief article proposal (up to 150 words) to plosntds [at] plos.org.

2. Open Access

PLOS applies the Creative Commons Attribution (CC BY) license to all works we publish. Under the CC BY license, authors retain ownership of the copyright for their article, but authors allow anyone to download, reuse, reprint, modify, distribute, and/or copy articles in PLOS journals, so long as the original authors and source are cited. No permission is required from the authors or the publishers.

3. Publication Fees

To provide Open Access, PLOS uses a business model to offset expenses—including those of peer review management, journal production and online hosting and archiving—by charging a publication fee to the authors, institutions or funders for each article published.

Publication fees vary by journal and are payable for articles upon acceptance.

PLOS believes that lack of funds should not be a barrier to Open Access publication. Since its inception, PLOS has provided individual fee support and institutional fee support programs. The current offering includes:

PLOS Global Participation Initiative (Low- and Middle-Income Country Assistance)

Authors' research which is funded primarily (50% or more of the work contained within the article) by an institution or organization from eligible low- and middle-income countries will receive partial (group 2 countries) or full (group 1 countries) fee funding paid by the PLOS Global Participation Initiative (GPI). Group 2 PLOS GPI country authors who need to request additional support should apply for PLOS Publication Fee Assistance instead of the PLOS GPI.

PLOS Publication Fee Assistance (PFA)

Publication Fee Assistance is intended for authors who demonstrate financial need. Information about an applicant's application status for fee assistance will not be disclosed to journal editors or reviewers. PLOS publication decisions will continue to be based solely on editorial criteria.

PLOS Institutional Fee Support Program

PLOS currently offers an institutional program to support Open Access scientific publishing. Participating institutions have arrangements with PLOS to administer payment for full publication fees for their institutions' authors. To be eligible, authors must be a corresponding author affiliated with the institution or agency in the Institutional Account Program (fully paid or restricted). (Special note to UK authors — certain institutions will restrict payment to cover for Wellcome Trust and RCUK research grant recipients only.) Authors who need to request additional support should apply for PLOS PFA.
Comparison of Visceral Leishmaniasis Diagnostic Antigens in African and Asian *Leishmania donovani* Reveals Extensive Diversity and Region-specific Polymorphisms

Tapan Bhattacharyya¹*, Marleen Boelaert², Michael A. Miles¹

¹ Faculty of Infectious and Tropical Diseases, London School of Hygiene and Tropical Medicine, London, United Kingdom; ²Department of Public Health, Institute of Tropical Medicine, Antwerp, Belgium

**Abstract**

**Background:** Visceral leishmaniasis (VL), caused by infection with *Leishmania donovani* complex, remains a major public health problem in endemic regions of South Asia, East Africa, and Brazil. If untreated, symptomatic VL is usually fatal. Rapid field diagnosis relies principally on demonstration of anti-*Leishmania* antibodies in clinically suspect cases. The rK39 immunochromatographic rapid diagnostic test (RDT) is based on rK39, encoded by a fragment of a kinesin-related gene derived from a Brazilian *L. chagasi*, now recognised as *L. infantum*, originating from Europe. Despite its reliability in South Asia, the rK39 test is reported to have lower sensitivity in East Africa. A reason for this differential response may reside in the molecular diversity of the rK39 homologous sequences among East African *L. donovani* strains.

**Methodology/Principal Findings:** Coding sequences of rK39 homologues from East African *L. donovani* strains were amplified from genomic DNA, analysed for diversity from the rK39 sequence, and compared to South Asian sequences. East African sequences were revealed to display significant diversity from rK39. Most coding changes in the 5' half of repeats were non-conservative, with multiple substitutions involving charge changes, whereas amino acid substitutions in the 3' half of repeats were conservative. Specific polymorphisms were found between South Asian and East African strains. Diversity of HASPB1 and HASPB2 gene repeat sequences, used to flank sequences of a kinesin homologue in the synthetic antigen rK28 designed to reduce variable RDT performance, was also investigated. Non-canonical combination repeat arrangements were revealed for HASPB1 and HASPB2 gene products in strains producing unpredicted size amplicons.

**Conclusions/Significance:** We demonstrate that there is extensive kinesin genetic diversity among strains in East Africa and between East Africa and South Asia, with ample scope for influencing performance of rK39 diagnostic assays. We also show the importance of targeted comparative genomics in guiding optimisation of recombinant/synthetic diagnostic antigens.

---

**Introduction**

Visceral leishmaniasis (VL) remains a major public health concern in many parts of the tropical world, with the great majority of the estimated 200,000 to 400,000 annual new cases found in South Asia, East Africa, and Brazil [1,2]. VL is caused by kinetoplastid protozoa of the *Leishmania donovani* complex. These are: *L. donovani* in South Asia and East Africa; *L. infantum*, mainly in Europe, the wider Mediterranean region, and in Latin America, where it was historically also known as *L. chagasi* but is now demonstrated to be synonymous with *L. infantum* originating from Europe [3].

*Leishmania* promastigotes, transmitted during bloodmeal feeding by female sandflies (*Phlebotomus* and *Lutzomyia* spp., in the Old and New World respectively), are internalised by local dermal macrophages and dendritic cells. Within these host cells, flagella are lost, and transformation into proliferative amastigote forms is followed by cell lysis, re-invasion of other cells, and parasite dissemination by the lymphatic and vascular systems, which can lead to infiltration of bone marrow and hepatosplenomegaly. In symptomatic cases, VL is fatal if untreated [4].

Parasitological diagnosis, by demonstration of amastigotes in spleen aspirates, approximates to a gold standard for VL diagnosis but is applied cautiously due to associated risk. Serological (anti-*Leishmania* antibody) tests include enzyme-linked immunosorbent assay (ELISA), indirect fluorescent antibody test (IFAT), and direct agglutination test (DAT) [5]. However, after drug treatment and cure current serological tests may still give positive results and therefore cannot readily diagnose relapse. Furthermore, such tests can also detect anti-leishmanial antibodies in asymptomatic
individuals living in endemic areas, but with no VL history or subsequent progression to VL [6].

Burns et al [7] identified a kinesin-related gene product, LcKin, as a candidate diagnostic antigen by screening a Brazilian L. infantum (L. chagasi) genomic library with serum of an L. donovani patient. A part of the coding sequence, comprising a 46aa region followed by 6.5x39aa repeats, forms the recombinant diagnostic protein rK39. In recent multicentre evaluations, the use of the rK39 in a lateral-flow immunochromatographic, rapid test format reported less success in East Africa than in the Indian subcontinent for point-of-care diagnosis of VL [8,9]. Underlying explanatory factors may reside in molecular divergence between East African L. donovani kinesin gene homologues and the Brazilian L. infantum (L. chagasi)-derived rK39 sequence, and/or may be due to differential immunocompetence and antibody levels produced among African and Asian human populations.

Studies on South Asian L. donovani strains using PCR primers based on LcKin have identified rK39 homologous sequences [10–12]. Gerald et al [13] reported the first East African (Sudanese) L. donovani kinesin homologue, LdK39. The first two of the 39-aa repeats of LdK39, flanked by sequences of the L. donovani antigens HASPB1 and HASPB2 [14], comprise rK28, a novel recombinant protein for diagnosis of VL, designed to be an improvement over rK39 [15–16]. HASPB proteins are expressed on the surface of infective promastigote and amastigote Leishmania life cycle stages [14]. The first 3x14aa repeats of HASPB1 are incorporated into rK28, along with the complete ORF of HASPB2, which includes three imperfect consecutive repeats, 2x14aa and 1x13aa. HASPB1 and HASPB2 correspond with K26 and K9, respectively [17], which were originally identified in L. infantum (L. chagasi) at the same time as the HASPBs, but were given different nomenclature. A recent comparison of rK26 and rK9 showed significantly lower diagnostic efficacy than rK28 [15].

Here we investigate whether molecular divergence in rK39 kinesin sequence homologues of East African L. donovani may contribute to lower rK39 diagnostic test success rates in East Africa. We analyse the rK39 homologues in a panel of East African L. donovani strains and compare their diversity against published South Asian sequences. In addition, we compare sequence diversity of HASPB1 and HASPB2 in East African and South Asian strains.

**Methods**

**L. donovani strains**

Table 1 lists the East African L. donovani strains used in this study. Strains were selected to represent genetic groups within the L. donovani complex in East Africa (Baleela et al, unpublished data; identified by multilocus sequence typing (MLST) and microsatellite analysis (MLMT)). Strains were cultured in αMEM medium supplemented by foetal calf serum (Sigma, UK), and genomic DNA was extracted from uncloned cultures using Gentra Puregene Tissue Core Kit A (Qiagen, UK). Uncloned cultures were specifically used here because the intention was to capture the diversity present within natural L. donovani populations. Table 2 lists the GenBank sequences derived in other studies [7,10–14,18–19] and used here for comparisons.

**Kinesin homologues**

PCR primers LdonK39F (gaacctgcaacgagctg) and LdonK39R (ctggctgctgccagt) were designed for this study based on a comparison of LeKin and LdK39 coding sequences (Figure 1A), and were targeted to amplify the 894 bp region of the L. donovani kinesin gene that is incorporated into the diagnostic antigen rK39. The level of conservation in the sequences encoding the 39-aa repeats predicts that primer LdonK39R would be expected to anneal to multiple sites within the kinesin gene template, generating multiple amplicons. Amplification reactions were performed in a total volume of 20 μl, and comprised of 1 x NH4 Reaction buffer supplemented with 1.5 mM MgCl2 (Bioline, UK), 200 μM dNTPs (New England Biolabs, UK), 10 pmol of each primer, and 1 U Biotaq DNA polymerase (Bioline). Amplification conditions were: 1 cycle of 94°C, 2 mins; 25 cycles of 94°C for 30 secs, 55°C for 30 secs, 72°C for 1 min; 1 cycle of 72°C for 5 mins. PCR products were separated by electrophoresis on 1.5% agarose gels (Bioline). Amplicons corresponding to rK39 homologues were excised and purified from gels using QIAquick Gel Extraction Kit (Qiagen), cloned into pGEM-T easy vector (Promega, UK), and transformed into XL1-blue E. coli on blue-white selection. Primers Sp6/T7 and M13for/rev were used to sequence from the vector (between 2–5 colonies per strain were taken forward for sequencing, except UGX-MARROW and SUDAN1, where due to difficulty in cloning the corresponding inserts only one clone was sequenced); in addition, LdonK39int (cgagcggctaaccagc), which binds to the 3′ end of the non-repeat region immediately upstream of the repeats, was used as an internal sequencing primer (Figure 1A). Sequences were analysed using BioEdit [20].

**HASPB**

PCR primers LdonHASPBlor (catataaaccctgagcc) and Ldon-HASPBrev (ctctctgtctctctctctctctctg) were designed for this study to flank the repeat regions of the HASPB1 ORF, amplifying a 1064 bp product (Figure 1B). Due to the identity between HASPB1 and HASPB2 at the primer binding sites, a 260 bp product would also be predicted to be amplified from HASPB2 by these primers (Figure 1C). Composition of PCR mix was as described above for kinesin, except that 40 μM dNTPs were used. Amplification conditions were: 1 cycle of 94°C, 2 mins; 25 cycles of 94°C for 30 secs, 50°C for 30 secs, 72°C for 1 min; 1 cycle of 72°C for 10 mins. PCR products were separated by electrophoresis on 1% agarose gels (Bioline). Amplicons were excised and purified from...
gels using QIAquick Gel Extraction Kit, and sequenced directly using the amplification primers. Sequences were analysed using BioEdit.

Accession numbers

Kinesin nucleotide sequences derived in this manuscript are available under GenBank accession numbers KC342866-KC342872. HASPB Nucleotide sequences derived in this manuscript are available under GenBank accession numbers KC342849- KC342865.

Results

East African L. donovani kinesin diversity

Multiple kinesin amplicons were produced using a combination of primers LdonK39F, which binds to the non-repeat region and LdonK39R, because the latter primer binds to nucleotide sequence that is conserved across the repeats. An example is shown in Figure 2. Sequencing of cloned amplicons containing the rK39 homologous sequences into plasmid vectors revealed the presence of nucleotide and predicted amino acid diversity among East African L. donovani strains. Table 3 shows the amino acid polymorphisms that were found among the East African strains, together with their divergence from L. infantum (L. chagasi) derived LcKin rK39, and alongside the GenBank sequence for L. donovani derived kinesin LdK39 used in rK28. Substitutions between a non-charged and a charged residue (D, E, H, K, R) in comparison with the LcKin rK39 sequence are shown underlined.

When the seven rK39 homologous repeats of all the East African strains were compared with the LcKin rK39 amino acid sequence, residues 2, 6, 10, 16 and 18 were each affected three or four times by substitutions involving charge changes. In contrast, although there were multiple substitutions in the latter half of the East African rK39 tandem repeats, especially affecting residues 21,

23, 27 and 39, none of these substitutions involved charge changes. Two tracts of the rK39 repeat, residues 11 to 15 and 28 to 34 were perfectly conserved between LcKin39 across all the East African strains examined and across all seven rK39 repeats within those strains.

Sequencing of multiple plasmid clones revealed the presence of alternative residues at single sites within single strains. This was notably widespread for the two strains Gilani and Hussen, in the case of Gilani, including several alternatives within the first and second repeats.

Comparison of L. donovani kinesin diversity between East Africa and South Asia

Figure 3 depicts the composite L. donovani kinesin polymorphisms for East Africa and South Asia and the divergence between the two geographic regions, in comparison with the LcKin rK39 derived from L. infantum (L. chagasi). The East African polymorphisms in Figure 3 incorporate the data obtained here together with the published LdKin (rK28) sequence. Substitutions between non-charged and charged residues (D2, E2, H+, K+, R+) compared to the LcKin rK39 sequence are shown underlined. East Africa-specific polymorphisms are boxed; South Asia-specific polymorphisms are circled.

In the 46aa non-repeat region the only divergence from L. infantum (L. chagasi) diagnostic LcKin rK39 was CysR Ser41, found among both South Asian and East African strains (Table 3). Throughout the 6.5×39aa repeats, there were polymorphisms divergent from the diagnostic LeKin rK39 that were unique to each region and other polymorphisms that were common to East Africa and South Asia. For example, Glu→Gly2 (Repeats 4, 5, 7) and Arg→His3 (Repeats 1, 2, 4) are found only in East Africa and South Asia respectively, whereas in Repeat 1, Ala→Ser21, Ala→Thr23, Ser→Met7, Thr→Ala39, which are all conservative changes found in the latter half of the repeats, were found in both regions. Indeed, as for the East African strains (Table 3) all such polymorphisms identified in the latter half of the repeats among South Asian strains are conservative, i.e., a non-charged residue is replaced by another non-charged residue; conversely, non-conservative substitutions between non-charged and charged residues are found in the first half of the repeats. Among the published South Asian sequences charges diverged from those in...

diagnostic LcKin rK39 at residue 4 (Gln→Arg; Repeats 2, 3, 4) and at residues 16, 17 and 18, for example uncharged to positive at these three sites in repeat 1 (Figure 3).

Comparison with *L. donovani* complex reference genomes

After the sequencing of the *L. infantum* reference genome [18], Downing et al [19] sequenced the Nepalese *L. donovani* strain BPK282/0cl4 as the reference genome for *L. donovani*. The sequence coding for the non-repeat 46-aa region of rK39 was submitted to NCBI BLAST against the reference genomes. For the *L. infantum* reference genome (Spanish, canine-isolated), there were no differences across the entire rK39 sequence, in accordance with this being the postulated source of *L. infantum* (*L. chagasi*) in South America [3]. For the genome sequence of BPK282, due to the repeat nature of the downstream region, only sequences of the first two repeats could be unequivocally aligned and these were incorporated into Figure 3 for comparisons with the individual repeat sequences generated here. From the unequivocal BLAST alignment information, BPK282 repeat 1 is the same as for rK39 except Thr→Ala39; in BPK repeat 2, where only the first 6 residues are unambiguously assembled, Gln→Arg4 is present.

*L. donovani* HASPB

PCR primers LdonHASPBfor and LdonHASPBrev were designed to bind unique sequences flanking the 22×14aa-repeat coding region of HASPB1 to produce a 1064 bp amplicon. However, with some of the strains studied here in addition to the 1064 bp product the smaller 260 bp amplicon corresponding to HASPB2 (Figure 1C) could also be seen: an example is shown for HU3 (LV9) in Figure 4. However, these primers unexpectedly gave amplicons of ~400–500 bp for some of the strains (Hussen, UGX-marrow, LRC-L57, MRC[L]3, SUKKAR 2) (Figure 4).

Comparisons with rK28 HASPB sequences

Strains HU3 (LV9), Gebre1, Gilani, LEM3582, LEM3556, and LEM3458, which gave 1064 bp amplicons, had identical sequences in their first 3×14aa repeats as the HASPB1 used in diagnostic rK28. However, subsequent repeats, not incorporated into rK28, were imperfect with polymorphic residues at certain sites, such as His→Arg6 (repeats 15, 18, 22) and Gly→Ala14 (repeats 5, 14, 17) for strains LEM3582, LEM3556, and LV9.

For those strains producing the predicted 260 bp amplicon of the HASPB2 homologue, (Figure 1) a comparison with the rK28 sequence identified a Gly residue inserted between Ala32 and Val33 preceding the imperfectly repeated 14/13aa region and a Pro→Gln66 substitution present after the 14/13aa region. The only polymorphism within the imperfectly repeated 14/13aa region, compared to rK28, was Lys→Glu66, at the third residue of first 14aa region, with a consequent charge change.

Interestingly, the strains producing unexpected ~400–500 bp amplicons (Hussen, UGX-marrow, LRC-57, SUKKAR 2, MRC[L]3) revealed on sequence analysis a HASPB1/HASPB2-like combination composition across their repeats, due to the presence of the central motifs that were HASPB1-like (HTQKN) or HASPB2-like (HAH-N). The HTQKN and HAH-N motifs were not consistently present in the same repeat numbers across these five strains and the HASPB1-like and HASPB2-like sections of the tandem repeat were not necessarily aggregated (Table 4). In the case of LRC/L57, both the 1064 bp (predicted HASPB1-homologue) and ~500 bp amplicons contained the HASPB2-like motif HAH-N. The Lys→Glu66 substitution at the third residue of

the first 14aa region, described above, was also present in those strains giving the ~400–500 bp amplicons.

### Figure 3. Polymorphisms among seven rK39 repeats of East African and South Asian strains show region-specific substitutions.
Changes between charged and non-charged residues are underlined. No residue entered at a particular site indicates conservation of that residue with the corresponding residue of diagnostic rK39. Where two alternative residues are indicated in smaller text these are not necessarily always within the same strain, for clarification compare with Table 3. Region-specific polymorphisms in each repeat are boxed (East Africa) or circled (South Asia). doi:10.1371/journal.pntd.0002057.g003

### Figure 4. Predicted (1064 bp, 260 bp) amplicons and unpredicted (~400–500 bp) amplicons with HASPB PCR primers LdonHASPBfor and LdonHASPBrev. Amplifications from strains HU3 (LV9), Hussen, UGX-MARROW, and LRC-L57, are depicted; mk = Hyperladder I. doi:10.1371/journal.pntd.0002057.g004

## Comparison with *L. donovani* reference genome

The sequence coding for the pre-repeat region of HASPB1 (not used in rK28, Figure 1A) was submitted to NCBI BLAST against the Nepalese *L. donovani* reference genome, to facilitate correct alignment. Due to the repeat nature of the downstream region, only the first two repeats of the reference genome could be unequivocally aligned for comparisons with the individual sequences generated here. The first two repeats of the reference genome showed the combination composition of central motifs HTQKN in repeat 1 (HASPB1-like) and HAH-N in repeat 2 (HASPB2-like). Thus, the South Asian reference genome has a HASPB1/2 combination structure like the four East African strains Hussen, UGX-marrow, LRC-L57, MRC(L)3, and the Iraqi SUKKAR 2, and with the same organisation of repeats 1 and 2 seen in the Kenyan strains LRC-57 and MRC(L)3.

**Discussion**

For VL there is a particular need for rapid diagnostic tests (RDTs) that can be unequivocally applied in endemic regions at primary care level and with only basic technical training. Of the available options for serological diagnosis of VL only the immunochromatographic rK39 assay can be considered a point of care test for field application. The IFAT requires a fluorescence microscope. Use of the DAT is constrained by the readout delay, the relative sophistication of the procedure and limited access to lyophilised antigen. In agreement with other studies, Boelaert et al [8] recommend the use of rK39 in South Asia, but report less satisfactory results from East Africa. One factor influencing regional differences in diagnostic performance may be divergence in kinesin gene homologues in East African L. donovani from the L. infantum (L. chagasi)-derived LcKin rK39 sequence. In an attempt to overcome the geographical limitations of the rK39 test a modified recombinant antigen, rK28, has been devised, incorporating segments of the HASPB antigen.

Analyses of L. donovani complex isolates with multiple molecular markers have revealed extensive genetic diversity with at least six distinct lineages, and both inter- and intra-lineage diversity. Furthermore, genotyping of isolates from endemic regions has shown an association between genotype and geographical origin [21–22]. Kuhls et al [22] used multilocus microsatellite typing (MLMT) for high resolution comparison of the six global L. donovani genetic lineages, and showed that allelic diversity in Africa was greater than in India; a subsequent MLMT study also described comparative homogeneity among South Asian L. donovani [23]. Thus, the relative homogeneity of South Asian L. donovani and greater diversity in East Africa, if mirrored in diversity of the kinesin gene, is one potential explanation of the more limited efficacy of diagnostic rK39 in East Africa.

Here we determined across a panel of East African strains the diversity of the kinesin repeat region homologous to that used in both the rK39 diagnostic antigen (repeats 1 to 6.5) and the rK28 recombinant antigen (repeats 1 and 2). We then compared this diversity to that among predetermined South Asian sequences.

Surprisingly, in view of the proven value of the rK39 RDT in South Asia, there is considerable amino acid sequence diversity among kinesin repeats 1 to 7 of South Asian strains as well as those from East Africa (Figure 3). Alternative residues at multiple sites suggested that Gilani and Hussen are heterozygous, although sequences were not obtained from DNA clones and therefore multiallotyping rather than heterozygosity cannot be excluded. Across all strains the diversity was particularly notable in the first half of each rK39 repeat, because it involved charge changes at residues 2, 6, 10, 16, and 18, with only a short stretch of consistently conserved residues (11 to 15). Such charge changes among the South Asian strains are very likely to disrupt antigenic epitopes, if present. As far as we are aware epitopes within or across adjacent rK39 repeats have not yet been precisely mapped. However, we would predict that the diagnostic epitopes lie in the latter half of the rK39 repeat, where, although there is extensive diversity, the changes are conservative, none involving charge, and there is one stretch of residues (28 to 34) that is entirely conserved across all isolates and across all seven repeats. This is consistent with the recent work of Costa et al [24] in which antigen prediction software led to the synthesis of a 22mer peptide (ESTTAAKMSAEQDRESTRATLE) encompassing the region of rK39 from residue 20 of repeat 3 to residue of 2 of repeat 4, a sequence which is also found in the next two repeats. In that study, the peptide was recognised in ELISA by Brazilian sera from symptomatic and asymptomatic canine VL and symptomatic human VL. However, our study shows that at least 5 of the residues within that 22mer are polymorphic in East Africa.

Kinesin repeat divergence from the rK39 diagnostic recombinant is complex, and some divergence is common to both South Asia and East Africa, for example at residues 7, 10, 21, 23 (Figure 3). Nevertheless, there were polymorphisms unique to each region, for example at residues 4, 16, and 18, consistent with the expectation that differential sensitivities of rK39 assays may be partially attributable to positional and physicochemical polymorphisms of the kinesin gene. The identification and confirmation of region-specific polymorphisms may be limited by the amount of sequence data so far available. Also diversity beyond the seven sequenced repeats of the kinesin tandem array may present a wider range of epitopes for immunological recognition.

The differential immunocompetence and antibody titres of East African and South Asian human populations in the context of VL remains to be thoroughly explored, as a major alternative or contributing explanation of variable rK39 test sensitivities. Interestingly a recent WHO/TDR evaluation [9] of a rapid diagnostic test based on rKE16 antigen, a LcKin homologue derived from an Indian L. donovani [10], reported markedly lower sensitivities against Brazilian and East African sera, compared to South Asian. The same evaluation [9] also reported a lower sensitivity of rK39-based tests with Brazilian sera. However, the
rK39 antigen is derived from a Brazilian *L. infantum (L. chagasi)* strain [7], which originated from Iberia in Europe and is considered to be relatively homogeneous, based on microsatellite typing [3]. Thus, kinesin diversity among Brazilian *L. infantum* should be explored further and comparative immune response levels among Brazilian and South American populations.

In the rK28 recombinant diagnostic antigen, designed to improve on performance of the rK39 test, highly conserved HASPB repetitive amino acid sequences flank the first two repeats of Ldk39, derived from an East African strain. Ace et al [14], following the work of McKean et al [25], amplified two homologues of the *L. major* Gene B protein from *L. donovani*, naming the ORF of the larger HASPB1 and that of the smaller HASPB2. Recombinant HASPB1 has been used in animal vaccine models [26–27], and HASPB has a role in *L. major* differentiation within the sandfly vector *P. papatasi* [28]. The PCR primers used in the current study, like those used by Alce et al [14], anneal to regions flanking HASPB repeat regions and generate two PCR products of predicted size corresponding to HASPB1 and HASPB2, compatible with the presence of two distinct HASPB1 and HASPB2 loci in the genome, as concluded for the *L. major* genome [29]. However, several strains produced unexpected sized amplicons with a mix of HASPB1 and HASPB2 motifs within these PCR products, indicating a structural reorganisation of HASPB in these strains. Similarly, Haralambous et al [30] in K26, a homologue of HASPB, also found unexpected amplicons for the Hussen strain as compared to Gebrel and Gilani. Nevertheless, despite this structural reorganisation, there was limited HASPB amino acid diversity across the strains. There was only one polymorphism compared to rK28 that involved a charge change, Lys→Glu in HASPB2, potentially affecting antigenicity. A recent study [31] reports HASPB repeat sequence diversity in *L. donovani* strains; a comparison with sequences derived here shows that among those East African strains producing unexpected sized amplicons (Table 4), there is the presence of repeat sequence types that are also predominant among Indian strains (PKEDDHAHNDDGG, PKEKDHQTNKDGDG, PKEDDDHAHNDGDG). In addition we find repeat types not reported from Indian strains, for example repeats beginning with Lys in place of Pro (Hussen, UGX-Marlow, SUKKAR 2), or ending in Val (LRC-L57, MRC/L5). We did not have patient samples from which to attempt direct amplification of kinesin and HASPB and confirm diversity in *viva*. Nevertheless the polymorphisms described here do not occur stochastically across strains but at sites of reported kinesin diversity, or in the case of the HASPB2, are consistent among strains (Ala→Gly, Val→Glu). Furthermore, the strains were cryopreserved, not subjected to prolonged passage in *vito*, and sequences were determined bi-directionally and/or repeated to confirm their validity.

We have undertaken the most comprehensive analysis of diagnostic kinesin and HASPB antigen diversity in East African strains to date. We show that there is extensive kinesin genetic diversity among strains and between East Africa and South Asia, with ample scope for influencing performance of rK39 diagnostic assays. Future research should both widen and focus the genomic comparisons between strains and also compare immune competence profiles among East African, Brazilian and South Asian populations as an alternative or contributory factor to variable RDT performance. There are broader implications from these findings. Firstly, we see the crucial importance of sustaining accessible collections of *Leishmania* strains representative of genetic lineages and global diversity. Secondly, due to present limitations in the capacity of whole genome sequencing to assemble complex antigen gene families, especially those comprised of repeated sequences, targeted analysis of individual strains is also necessary for these comparisons of genetic diversity. Thirdly, it is evident that comparative genomics has a vital role in guiding the optimisation of recombinant or synthetic diagnostic antigens. Not only are even better diagnostic tests needed for diagnosis of VL, but biomarkers are urgently required to distinguish asymptomatic cases, asymptomatic infections at risk or not of progression to VL, and post-treatment outcome (relapse versus cure).

Acknowledgments

We thank Isabel Mauricio and Rania Baleela for guidance on choice of strains, Matthew Yeo for contributing to parasite culture, and for their constructive comments on the manuscript. We also thank François Chappuis for his comments. The authors are also grateful to anonymous reviewers for their improvements to the manuscript.

PUBLICATIONS ARISING: Leishmania donovani complex and visceral leishmaniasis

Key points, novel results and implications

- As described in ANNEX 4 Bhattacharyya et al., 2013 recent multi-centre trials of the rK39 RDT have shown much lower sensitivities in East Africa than the South Asia, and the extent and nature of Leishmania antigen diversity was examined as a possible cause.
- Here, the relevance of the human immunoglobulin response by patients from endemic regions in Sudan and India is examined by comparative serology against Leishmania lysates originating from both regions.
- ELISA plates were coated with whole cell lysates of Sudanese and Indian L. donovani strains, such that each strain was coated on half of each plate. VL patient plasma from the different endemic areas of Bihar (India) and Gedaref (Sudan) were then titrated against the lysates, for comparison of anti-Leishmania response.
- Composite results for each cohort (India n=36, Sudan n=36) were analysed by plotting 1/log plasma dilution of the serial titration against ELISA readout. A striking finding was that the Sudanese cohort produced much lower IgG titres than the Indian, as measured by 50% end titres. This was observed regardless of antigen source, patient age or sex (p<0.0001).
- This work shows that a possible reason for the lower sensitivity of the rK39 RDT in East Africa is the lower IgG response generated, which may be due to genetic/ethnic, nutritional or environmental factors.

Candidate’s contribution:

The candidate prepared the antigen and co-performed, via supervision of a LSHTM Masters degree research student project, the ELISAs described in the publication. The candidate prepared the first draft of the manuscript, which was accepted for publication by PLoS Negl Trop Dis in December 2013 following academic peer review.
To further serological studies on VL, and in the context of the existing literature, the relationship between IgG subclass responses in VL patients of different clinical status was an additional area of interest. That work is described in the following section (ANNEX 5 Bhattacharyya et al., 2014).
COVER SHEET FOR EACH ‘RESEARCH PAPER’ INCLUDED IN A RESEARCH THESIS

Please be aware that one cover sheet must be completed for each ‘Research Paper’ included in a thesis.

1. For a ‘research paper’ already published
   1.1. Where was the work published? PLOS NEGLECTED TROPICAL DISEASES
   1.2. When was the work published? 2014
      1.2.1. If the work was published prior to registration for your research degree, give a brief rationale for its inclusion

   1.3. Was the work subject to academic peer review? YES

   1.4. Have you retained the copyright for the work? Yes / No
      If yes, please attach evidence of retention.
      If no, or if the work is being included in its published format, please attach evidence of permission from copyright holder (publisher or other author) to include work

2. For a ‘research paper’ prepared for publication but not yet published
   2.1. Where is the work intended to be published?

   2.2. Please list the paper’s authors in the intended authorship order

   2.3. Stage of publication – Not yet submitted / Submitted / Undergoing revision from peer reviewers’ comments / In press

3. For multi-authored work, give full details of your role in the research included in the paper and in the preparation of the paper. (Attach a further sheet if necessary)
   I prepared the antigen and co-performed, in supervision of a LSHTM MASTERS RESEARCH PROJECT, THE ELISA DESCRIBED IN THE PUBLICATION. I PREPARED THE FIRST DRAFT OF THE MANUSCRIPT.

2. Open Access

PLOS applies the Creative Commons Attribution (CC BY) license to all works we publish. Under the CC BY license, authors retain ownership of the copyright for their article, but authors allow anyone to download, reuse, reprint, modify, distribute, and/or copy articles in PLOS journals, so long as the original authors and source are cited. No permission is required from the authors or the publishers.

3. Publication Fees

To provide Open Access, PLOS uses a business model to offset expenses—including those of peer review management, journal production and online hosting and archiving—by charging a publication fee to the authors, institutions or funders for each article published.

Publication fees vary by journal and are payable for articles upon acceptance.

PLOS believes that lack of funds should not be a barrier to Open Access publication. Since its inception, PLOS has provided individual fee support and institutional fee support programs. The current offering includes:

PLOS Global Participation Initiative (Low- and Middle-Income Country Assistance)

Authors’ research which is funded primarily (50% or more of the work contained within the article) by an institution or organization from eligible low- and middle-income countries will receive partial (group 2 countries) or full (group 1 countries) fee funding paid by the PLOS Global Participation Initiative (GPI). Group 2 PLOS GPI country authors who need to request additional support should apply for PLOS Publication Fee Assistance instead of the PLOS GPI.

PLOS Publication Fee Assistance (PFA)

Publication Fee Assistance is intended for authors who demonstrate financial need. Information about an applicant’s application status for fee assistance will not be disclosed to journal editors or reviewers. PLOS publication decisions will continue to be based solely on editorial criteria.

PLOS Institutional Fee Support Program

PLOS currently offers an institutional program to support Open Access scientific publishing. Participating institutions have arrangements with PLOS to administer payment for full publication fees for their institutions’ authors. To be eligible, authors must be a corresponding author affiliated with the institution or agency in the Institutional Account Program (fully paid or restricted). (Special note to UK authors — certain institutions will restrict payment to cover for Wellcome Trust and RCUK research grant recipients only.) Authors who need to request additional support should apply for PLOS PFA.
Significantly Lower Anti-*Leishmania* IgG Responses in Sudanese versus Indian Visceral Leishmaniasis

Abstract

**Background:** Visceral leishmaniasis (VL), a widely distributed systemic disease caused by infection with the *Leishmania donovani* complex (*L. donovani* and *L. infantum*), is almost always fatal if symptomatic and untreated. A rapid point-of-care diagnostic test for anti-*Leishmania* antibodies, the rK39-immunochromatographic test (rK39-ICT), has high sensitivity and specificity in South Asia but is less sensitive in East Africa. One of the underlying reasons may be continent-specific molecular diversity in the rK39 antigen within the *L. donovani* complex. However, a second reason may be differences in specific IgG anti-*Leishmania* levels in patients from different geographical regions, either due to variable antigenicity or immunological response.

**Methodology/Principal Findings:** We determined IgG titres of Indian and Sudanese VL patients against whole cell lysates of Indian and Sudanese *L. donovani* strains. Indian VL patients had significantly higher IgG titres against both *L. donovani* strains compared to Sudanese VL patients (p<0.0001). Mean reciprocal log₁₀ 50% end-point titres (1/log₁₀t₅₀) were i) 3.80 and 3.88 for Indian plasma and ii) 2.13 and 2.09 for Sudanese plasma against Indian and Sudanese antigen respectively (p<0.0001). Overall, the Indian VL patients therefore showed a 46.8–61.7-fold higher mean ELISA titre than the Sudanese VL patients. The higher IgG titres occurred in children (<16 years old) and adults of either sex from India (mean 1/log₁₀t₅₀: 3.60–4.15) versus Sudan (mean 1/log₁₀t₅₀: 1.88–2.54). The greatest difference in IgG responses was between male Indian and Sudanese VL patients of ≥16 years old (mean 1/log₁₀t₅₀: 4.15 versus 1.99 = 144-fold (p<0.0001)).

**Conclusions/Significance:** Anti-*Leishmania* IgG responses among VL patients in Sudan were significantly lower than in India; this may be due to chronic malnutrition with Zn²⁺ deficiency, or variable antigenicity and capacity to generate IgG responses to *Leishmania* antigens. Such differential anti-*Leishmania* IgG levels may contribute to lower sensitivity of the rK39-ICT in East Africa.

Introduction

The great majority of the estimated 200,000 to 400,000 annual new cases of visceral leishmaniasis (VL) occurs in six countries, with India having the highest estimated incidence in the world (146,700 to 282,800/year), Sudan having the highest in Africa (15,700 to 30,300/year) and Brazil having the highest in the Americas (4,200 to 6,300/year) [1]. In South Asia and East Africa, VL is caused by the kinetoplastid protozoan *Leishmania donovani*, transmitted by the sandfly species *Phlebotomus argentipes* in South Asia and *P. orientalis* and *P. martinii* in East Africa. Following inoculation into the human host, the parasite disseminates through the lymphatic and vascular systems. Some infected individuals remain asymptomatic, but full-blown symptomatic VL with bone marrow infiltration and hepatosplenomegaly is almost always fatal if untreated [2]. The demonstration of *L. donovani* amastigotes in lymph node, spleen or bone marrow tissue smears is the definitive diagnostic method for infection, however due to the invasive nature and the operational difficulties associated with these procedures, serological assays have been developed. Serological [anti-*Leishmania* antibody] tests include the enzyme-linked immunosorbent assay (ELISA), indirect fluorescent antibody test (IFAT) and the direct agglutination test (DAT) [3,4]. However, these antibody detection tests remain positive for several months to years after drug treatment and cure and therefore cannot readily diagnose relapse;
Author Summary

Visceral leishmaniasis (VL) is a systemic disease with highest prevalence in South Asia, East Africa, and Brazil. VL is caused by protozoan parasites of the *Leishmania donovani* complex, transmitted to humans when an infected sandfly takes a bloodmeal. Within the human host, the parasites replicate within cells, particularly of bone marrow and spleen. Without effective treatment, symptomatic VL is usually fatal. Correct treatment depends on accurate diagnosis, which is by detection of parasites or specific antibodies. The rK39 rapid diagnostic test for antibody is highly sensitive in South Asia but less so in East Africa, for poorly understood reasons. Here, we have directly compared the anti-*Leishmania* antibody response in groups of VL patients from India and Sudan. We found a strikingly higher anti-*Leishmania* antibody response in Indian compared to Sudanese patients, which was also seen when further analysed by age and sex of the patients. Thus in addition to parasite factors, we have shown that differences in antibody levels may contribute to the lower sensitivity of antibody-based diagnosis for VL in Sudan.

such tests can also be positive in asymptomatic individuals living in endemic areas and exposed to *L. donovani* infection yet with no history of VL or subsequent progression to VL.

The lateral-flow rapid diagnostic ‘point-of-care’ immunochromatographic test (ICT) format based on the rK39 antigen derived from a Brazilian isolate of *Leishmania infantum* (historically known as *L. chagasi*) [5] has demonstrated high levels of sensitivity in South Asia but is less effective in East Africa for diagnosis of VL [6,7]. A new ICT, based on the synthetic gene rK28, has recently been developed to overcome these limitations [8,9], and is currently under evaluation. Underlying explanatory factors for the different levels of rK39 diagnostic success observed across geographical regions may be molecular divergence between East African *L. donovani* kinesin gene homologues and the Brazilian *L. infantum* (*L. chagasi*)-derived rK39 sequence [10], and/or may be due to quantitative differences in the IgG titres generated against the rK39 antigen between South Asian and East African VL-endemic populations. Here, we compare anti-*L. donovani* IgG titres in cases of active VL in children and adults of each sex from India and Sudan against whole cell lysates of *L. donovani* strains from both countries. We find striking differences between the anti-*Leishmania* IgG titres of the two human populations.

Methods

Ethics statement

In India, comparative serology was approved by the Ethics Committee of the Banaras Hindu University, Varanasi, India. In Sudan the protocols were approved by the Ethical Research Committee, Faculty of Medicine, University of Khartoum and the National Health Research Ethics Committee, Federal Ministry of Health. Written informed consent was obtained from all adult subjects included in the study, or from the parents or guardians of individuals less than 18 years of age. This research was also covered by the London School of Hygiene and Tropical Medicine Ethics Committee approval of the EC NIDIA project.

Study populations

Sudan: plasma samples were obtained upon clinical presentation from active cases of VL in the Gedaref region in eastern Sudan between July and September 2011. Patients were diagnosed as positive for VL by a combination of bone marrow aspiration, lymph node aspiration, or serology. India: plasma samples were obtained upon clinical presentation from active cases of VL in Bihar state, north-eastern India after 2009. Active VL patients were diagnosed by identification of parasitologically-positive splenic aspirates. All samples in Sudan were transported by continuous cold chain with samples maintained at 4°C, to the research laboratory at Suba University Hospital and there stored at −80°C; similarly all samples in India were cold chain transported at 4°C to the laboratory at Banaras Hindu University and stored at −80°C.

Antigen preparation

Strains of *L. donovani* originating from Sudan (MHOM/SD/97/ LEM3458) and India (MHOM/IN/80/DD8) were cultured in αMEM (Sigma, UK) supplemented as described [11]. Mid-to-late log phase cultures were washed three times in phosphate-buffered saline (PBS), followed by three cycles of flash-freezing in liquid nitrogen and thawing in a cold water bath. Subsequently, cells were subjected to three 30 sec 12-micron sonication cycles on ice at 30 second intervals using a Soniprep 150 sonicator (MSE, UK). Sonicates were centrifuged at 12,000×g for 1 min, and the supernatant used as antigen. Protein concentrations in these lysates were determined using the BCA Protein Assay kit (Fisher Scientific, Loughborough, UK).

Anti-*Leishmania donovani* ELISA

The indirect *L. donovani* ELISA was performed using relatively low antigen concentrations (0.2 µg/well) established by prior ELISA checkerboard titrations (not shown), with the intention of increasing ability to discriminate between patients generating high and low IgG antibody responses. Lysates of the *L. donovani* DD8 (Indian) and LEM3458 (Sudanese) strains, diluted to 2 µg/ml in 35 mM NaHCO3/15 mM NaCO3 buffer (pH 9.6), were separately added at 100 µl/well to 48 wells (A to H 1–6 and A to H 7–12) (see Figure 1) of Immulon 4HB ELISA plates (VWR, Lutterworth, UK) and incubated overnight at 4°C. After washing the plates three times using PBS containing 0.05% (vol/vol) Tween 20 (Sigma, Gillingham, UK) (PBST), they were blocked using 200 µl/well PBST containing 2% skimmed milk powder (Premier International Foods, Spalding, UK) (PBST) at 37°C for 2 hr. After washing three times with PBST, serial four-fold 1:400 to 1:25,600 dilutions of VL plasma samples (Table 1, Figure 1) (100 µl/well) in PBST were added to the plates and incubated at 37°C for 1 hr. Plasma samples from the two endemic countries were assayed on the same plate against antigens of both Indian and Sudanese strains and were matched for sex and age groups as shown in Figure 1. Following six PBST washes, a 1:5,000 dilution of peroxidase-labelled goat anti-human IgG (H+L) (Jackson ImmunoResearch, West Grove, USA) prepared in PBST was added at 100 µl/well and the plates incubated at 37°C for 1 hr. Following six PBST washes, 50 mM phosphate/citrate buffer (pH 5.0) containing 2 mM o-phenylenediamine HCl and 0.007% (vol/vol) H2O2 (Sigma, UK) was added at 100 µl/well and incubated in the dark at room temperature for 15 minutes. The substrate reactions were then stopped by the addition of 2 M H2SO4 (30 µl/well) and the ELISA plates were read at 490 nm (Spectra Max 190, Molecular Devices, Sunnyvale, USA). Coefficients of variation (mean positive control readings (n = 4)/standard deviation of positive control x 100) at dilutions of 1/400 and 1/1600 were calculated from simultaneous duplicate plates for both Indian and Sudanese sera (most coefficients of variation were less than 1%). Reference positive plasma controls were also used on every plate (Figure 1). Samples that gave coefficients of
Lower IgG Responses in Sudanese versus Indian VL

Figure 1. Design of assay for comparative ELISA serology. Serial four-fold dilutions of plasma samples from Indian and Sudanese VL patients were reacted with whole cell lysates of *L. donovani* strains isolated from each country. Identically formatted plates were run in all cases. Unlabelled wells were not used.

doi:10.1371/journal.pntd.0002675.g001

These plasma samples were chosen in preliminary assays as having median responses against the lysate obtained from the *L. donovani* strain isolated from the corresponding region (data not shown). To

maximize the chances of identifying differences in the IgG responses against the two different L. donovani strains (Figure 2) and between Indian and Sudanese VL patients of each sex and age group (> or < 16 years old), the highest mean absorbance (Absmax) value was determined for each data set, from which the Absmax/2 was determined for calculating the mean reciprocal log10 50% end-point (1/log10t50) ELISA titres. This methodology has been recommended for comparisons between high, low and non-classical IgG responses of acute and convalescent phase samples from both individuals and patient groups infected with another pathogen [12,13]. This approach is more accurate than determining ELISA titres as either: i) single end-point values located on the very trailing slope of the ELISA sigmoid curve (e.g. values that are 2 standard deviations above the mean obtained using negative control sera) or ii) the mean absorbance values obtained using single serum dilutions (e.g. 1/100) [12]. In the latter case, the limited use of absorbance values results in a low dynamic range of data for comparisons [12].

Statistical analyses

Two sided independent sample t-tests were used to analyse the data (SPSS INC. Armonk, NY: IBM Corp). Normality was assessed using a three tiered approach. Shapiro-Wilk tests were conducted first with subsequent evaluation of the data through visual assessment and by calculating a z-score for skewness (ZSkewness = Skewness-0/SE Skewness) as proposed by Ghasemi and Zahediasl [14]. In the event of a violation of the assumption of homogeneity of variance (homscedasticity), SPSS calculated a corrected p value. Significance was set at the 5% level.

Results

Table 1 summarises the age and sex compositions of the Indian and Sudanese VL patients who provided plasma for comparisons of serological responses between the two endemic regions.

Comparison of Indian and Sudanese IgG isotype responses

The mean overall Sudanese (n = 36) and Indian (n = 36) active VL patients’ IgG responses, at each plasma dilution, against lysates of L. donovani strains isolated from each endemic area, with 95% confidence intervals (CIs) are shown in Figure 2. In a few instances, the unforeseen low Sudanese titres required minor extrapolation of curves to determine specific 1/log1050% end-point titres but since homoscedasticity was obtained in each case a correction factor was not required. Similar high mean maximum absorbance (Absmax) values were obtained for the Indian VL patients against both the Indian and Sudanese L. donovani strains. However the Indian VL patients showed significantly higher IgG titres against both the Sudanese (mean 1/log10t50: 3.88) and Indian (mean 1/log10t50: 3.80) L. donovani strains than the Sudanese VL patients (mean 1/log10t50: 2.09 and 2.13 respectively) (Figure 2A and B, Table 2; two-sided independent sample t-tests for both L. donovani strains: p, 0.0001). Thus, overall the Indian VL patients generated 46.8–61.7-fold higher IgG titres than the Sudanese patients against the L. donovani strains (Table 2).

We further assessed whether there were differences in anti-L. donovani IgG titres generated by the male and female Indian and Sudanese VL patients of less than or greater than 16 years old against both L. donovani strains. We again used the mean highest absorbance (Absmax) value for each data set (Figure 3A to D) to maximize the identification of differences in the mean IgG responses, from which the Absmax/2 value was determined for interpolating the mean 1/log10t50 IgG ELISA titres. We observed that the male VL patients of ≥16 years old from India showed higher Absmax values against both the Sudanese (Absmax 3.34) and Indian (Absmax 3.33) antigens than the female Indian VL patients of the same age group (Absmax 3.11 and 2.99, respectively) (Figure 3C and D). This difference was less in the male and female Indian VL patients of <16 years old (Figure 3A and B). Importantly, the Sudanese male and female children (<16 years old)
old) and adults all generated lower mean IgG ELISA titres against both *L. donovani* strains than the corresponding Indian VL patient sex/age groups (Figure 3A to D). These differences ranged from 11.5 to 144-fold (Table 2).

The Sudanese male VL patients less than 16 years old showed the lowest fold-differences compared to the Indian male VL patients of the same age group (12.9-fold and 11.5-fold against the lowest fold-differences compared to the Indian male VL patients of the same age group (144-fold).

### Discussion

According to a recent report from the World Health Organisation, among the research priorities for human diseases caused by infection with kinetoplastid protozoa is research on diagnostics for case detection and characterisation [13]. For many years, the rK39 antigen has been the only rapid diagnostic ICT in a lateral flow system that is readily applicable for field diagnosis of VL and that can be used with minimal training with no other equipment or reagent. Despite high levels of sensitivity in South Asia, the rK39 ICT has shown lower efficacy in East Africa, for reasons that are not fully understood. The recent rK28 ICT, based on 2×39 amino acid repeats of a Sudanese *L. donovani*-derived kinesin homologue of rK39, flanked by HASPB sequences, has been developed in an attempt to overcome the differential sensitivity of rK39. Reduced efficacy in East Africa has also been reported for a diagnostic test using another *L. donovani* antigen, rKE16 [7].

Different sensitivities of the rK39 ICT in South Asia and East Africa may be explained by molecular divergence in diagnostic antigen sequences of geographically disparate *L. donovani* strains and/or reflect the different levels of overall IgG anti-*Leishmania* response between human populations in VL endemic areas. We have assessed the first of these factors, and demonstrated substantial and regional specific antigen diversity [10], an observation subsequently reported by others [16].

Differential serological responses among different ethnic groups within the same geographical region have been reported previously, for both bacterial and protozoal pathogens, although generally without understanding of the genetic/biological explanations. Higher responses were found against *Helicobacter pylori* in non-Japanese Brazilians than Japanese Brazilians [17]; *Streptococcus pyogenes* superantigen in Polynesian than New Zealand Europeans [18]; *Plasmodium falciparum* in Fulani than sympatric ethnic groups in Burkina Faso [19]; *P. falciparum* in Austro-Asiatic than Tibeto-Burman groups in north-east India [20]. Jensen et al [21] reported comparatively higher anti-*Plasmodium* titres in subjects from Flores (Indonesia) than in counterparts from southern Sudan. In the UK, higher IgG levels were found in South Asian patients compared to European counterparts in the context of cardiovascular disease [22].

Here, we used comparative analysis of serological responses, as applied elsewhere [12,13] to assess accurately differences in IgG titres between VL patient cohorts from Bihar (India) and Gedaref (Sudan). We have clearly shown that active VL patients from India generated significantly higher anti-*L. donovani* IgG responses against whole cell lysates of both Indian and Sudanese parasite strains than active VL patients from Sudan. This may contribute to the reduced sensitivity of the commercial rK39 ICT assay with Sudanese versus Indian VL patients. We used soluble antigens from *Leishmania* whole cell lysates in the comparative ELISAs. On western blots human VL serum antibodies recognise multiple antigens in such lysate preparations (data not shown). It is therefore likely that Sudanese patients with active VL had reduced IgG titres against several *L. donovani* promastigote antigens; we have not yet determined whether the response to particular antigens is depleted. Thus, it may be challenging to identify *L. donovani* antigens that provide adequately high sensitivity and specificity for East Africa. Whilst it would be of interest to extend these comparisons to include IFAT, results from ELISA and IFAT generally accord, and we therefore anticipate that the two tests will give compatible data [23]. Detection of antigens in urine may provide an alternative, non invasive approach, possibly giving prognostic information [24,25]. In the same multi-centre trial comparing rK39 dipstick sensitivity and specificity across South Asia and East Africa, Boelaert et al. [6] also compared the KAtex® test, which detects a *Leishmania* carbohydrate antigen in urine.
Sensitivities in both regions were described as moderate to very low, with the lowest in India and Nepal, although higher sensitivities have been recently reported from Bangladeshi studies [28–30].

We have not yet assessed antibody levels in patients with post-kala azar dermal leishmaniasis (PKDL). This is of interest because PKDL is a sequela of VL that displays markedly different epidemiological features between regions, in Sudan occurring at a higher frequency (>50%) and much sooner after VL than in India (<10%) [31]. In Sudan and India the plasma was collected at time of clinical presentation of VL, and no obvious differences in symptoms between the two cohorts were observed; further comparisons would benefit from more precise grading of clinical severity.

Whilst the active VL patient numbers used in our analysis were relatively low, Indian males 16 years old with active VL generated higher IgG responses than females of the same age group, whereas Sudanese male VL patients ≥16 years old generated lower IgG responses than females of the same age group. These trends were not apparent in Indian or Sudanese patients <16 years old. Differences in infection between males and females in late teenage years and in adults may be attributable to increased susceptibility of young and adult men [32]; testosterone increases L. donovani infection in macrophages [33]. In Sudan VL is a disease of extreme poverty with high incidence associated with chronic malnutrition, displacement of populations and lack of health care [1,34–39]. Particular ethnic groups, possibly with greater genetic susceptibility, may be more affected within the ethnically mixed Sudanese population [40,41].

Malnutrition is known to reduce both human innate and acquired immune responses against parasitic diseases such as VL [42,43]. Experimental models of protein, zinc and iron malnutrition have shown reduced immune responses in L. infantum infected mice and increased early visceralisation [44,45]. Of these, even mild zinc deficiency has been extensively reported to: i) reduce T- and B-cells in the blood and lymphoid tissues of humans, non-human primates and other animals, ii) dramatically reduce both T- and B-cell numbers in the bone marrow by >75%, iii) dramatically reduced B-cell IgG production, particularly to T-dependent antigens, by 90% and iv) reduce both T- and B-cell proliferation, resulting in depletion through apoptosis [46]. More specifically, zinc deficiency in mice was shown to block the

Figure 3. IgG anti-Leishmania responses are higher in Indian VL regardless of age, sex or antigen source. The mean IgG responses and 95% CI are shown for Indian (purple and orange lines) and Sudanese (blue and green lines) active VL patients against lysates of L. donovani strains isolated from Sudan (A & C) or India (B & D). Comparative mean 1/log_{10} IgG titres and fold-differences are given in Table 2.

doi:10.1371/journal.pntd.0002675.g003
Lower IgG Responses in Sudanese versus Indian VL

development of bone-marrow pre-B and immature B-cells, resulting in reduced B lymphocytes in the spleen; pre-natal zinc deficiency in monkeys and mice reduced lymphocyte numbers and IgG concentrations and produced long-term suppression of IgM, IgA and IgG. Zinc deficiency in mice also resulted in reduced B-cell responses to recall antigens with which they had previously been inoculated, thereby suggesting that T- and B-cell depletion resulted in impaired immunological memory [46]. Thus, malnutrition with zinc deficiency, even if relatively mild and previously encountered may play an important role in the significantly lower IgG titres of the Sudanese patients.

Human interleukin-2 (IL-2) and signalling through its receptor (IL-2Rα) play a critical role in both T- and B-cell proliferation and induce the expression of the IL-2Rα gene in B cells, thereby increasing B-cell responses to IL-2, antibody heavy and light chain expression and antibody secretion [47]. Thus, single nucleotide polymorphisms in the genes encoding IL-2 and its receptor (IL-2Rα or IL-2Rβ) chains significantly affect human IgG titres in response to both inactivated and live attenuated vaccines (e.g. the live attenuated measles-mumps-rubella (MMR) vaccine) [48,49]. While there have not been similar studies performed on Sudanese populations, VL patients in eastern Sudan had a significant association with two SNPs in the IL-2Rβ gene, one of which encoded a non-conserved amino acid substitution (G245R) in the proximal membrane domain that was very likely to affect IL-2 signalling [50]. Thus, these SNPs and others located in the genes that affect IL-2 expression, function and responses may have contributed to the reduced IgG responses of Sudanese VL patients observed in our study.

Human leukocyte antigen (HLA) polymorphisms in the genes encoding the MHC class II (HLA-DR, -DP and -DQ) molecules are known to have significant effects on IgG responses to vaccines [48], infectious diseases, cancer, asthma and autoimmune diseases [51–53]. Early studies did not however find a significant association of HLA class II polymorphisms in VL patients in either Tunisia or Brazil [54,55]. By contrast, in a more recent study performed using VL patients’ samples from Brazil and India, HLA-DRB1 and HLA-DQA1 were the only genes associated with VL risk in both populations [56] but comparisons of anti-L. donovani IgG titres between these groups or the control groups were not performed. Since no similar HLA studies have been performed on Sudanese VL patients, it is presently not yet known whether polymorphisms in these genes may have contributed to the significantly lower IgG titres observed in the Sudanese versus Indian VL patients found in our study.

Thus, the significant differences in the anti-L. donovani IgG titres found here between the Indian and Sudanese VL patients in this study may result from a combination of environmental and genetic factors, in which malnutrition with Zn2+ deficiency, differences in IL-2 responses due to polymorphisms in IL-2 and its receptor (IL-2Rα and IL-2Rβ) genes and possibly HLA-DRB1 and HLA-DQA1 genes are to date the most likely candidates.

We have presented here a direct ELISA comparison of serological responses between VL patients from different endemic regions (Sudan and India), and have shown a clear difference in the levels of IgG anti-Leishmania antibodies. Comparative serological responses could also be extended to samples from Brazilian cases of VL to investigate their contribution to reported lower sensitivity with rK39-based ICTs [7], despite this diagnostic antigen being derived from a Brazilian L. infantum (L. chagasi), dispersed from Iberian Europe [57]. Our data suggest that the relative levels of ability to mount a humoral response against Leishmania antigen between the different human populations may be a significant contributory factor in the differing levels of sensitivity reported for rapid diagnostic tests applied in both regions, and argue for the design and development of a test more suited to East Africa, guided by comparative genomics [10].

Acknowledgments

PUBLICATIONS ARISING: *Leishmania donovani* complex and visceral leishmaniasis

**Key points, novel results and implications**

- Current definitions of successful cure following chemotherapy for visceral leishmaniasis are based on clinical definitions. The identification of biomarkers which can indicate therapeutic outcome (cure or relapse), especially in the form of a point-of-care rapid assay, has been listed by WHO as a knowledge gap and research priority (WHO, 2012).  

- Here, the association of IgG subclass with clinical status in VL was investigated by ELISA using Indian and Sudanese samples, initially from unpaired samples from pre-treatment patients, those deemed cured after therapy, and those deemed relapsed. Levels of IgG1 (and to a lesser degree IgG3) were elevated in the pre-treatment and relapsed groups, compared to cured (p<0.0001).  

- When using paired pre- and post-treatment samples from patients considered cured, the decrease in IgG1 was not significant in the immediate few weeks following treatment, but was greatly diminished in the 6-month post treatment samples in cohorts compared to day 0 (p = 0.0032) or day 15 (p<0.0001).  

- Two prototype lateral flow immunochromatographic RDTs were developed to detect IgG1 levels following VL treatment: more than 80% of the relapsed VL patients were IgG1 positive; at least 80% of the cured VL patients were IgG1 negative (p <0.0001).  

- Thus this work demonstrated that six months after treatment of active VL, elevated levels of specific IgG1 were associated with treatment failure and relapse, whereas no IgG1 or low levels were detected in cured VL patients. A lateral flow RDT was successfully developed to detect anti-VL IgG1 levels as a potential biomarker of post-chemotherapeutic relapse.
Candidate’s contribution:

The candidate prepared the antigen and co-performed, in supervision of LSHTM Masters degree research student projects, the ELISAs described in the manuscript. The candidate prepared the first draft of the manuscript, requiring the coherent compilation of a number of data sets and a comprehensive review of the literature, and which was accepted for publication by *PLoS Negl Trop Dis* in September 2014.

2. Open Access

PLOS applies the Creative Commons Attribution (CC BY) license to all works we publish. Under the CC BY license, authors retain ownership of the copyright for their article, but authors allow anyone to download, reuse, reprint, modify, distribute, and/or copy articles in PLOS journals, so long as the original authors and source are cited. No permission is required from the authors or the publishers.

3. Publication Fees

To provide Open Access, PLOS uses a business model to offset expenses—including those of peer review management, journal production and online hosting and archiving—by charging a publication fee to the authors, institutions or funders for each article published.

Publication fees vary by journal and are payable for articles upon acceptance.

PLOS believes that lack of funds should not be a barrier to Open Access publication. Since its inception, PLOS has provided individual fee support and institutional fee support programs. The current offering includes:

**PLOS Global Participation Initiative (Low- and Middle-Income Country Assistance)**

Authors' research which is funded primarily (50% or more of the work contained within the article) by an institution or organization from eligible low- and middle-income countries will receive partial (group 2 countries) or full (group 1 countries) fee funding paid by the PLOS Global Participation Initiative (GPI). Group 2 PLOS GPI country authors who need to request additional support should apply for PLOS Publication Fee Assistance instead of the PLOS GPI.

**PLOS Publication Fee Assistance (PFA)**

Publication Fee Assistance is intended for authors who demonstrate financial need. Information about an applicant's application status for fee assistance will not be disclosed to journal editors or reviewers. PLOS publication decisions will continue to be based solely on editorial criteria.

**PLOS Institutional Fee Support Program**

PLOS currently offers an institutional program to support Open Access scientific publishing. Participating institutions have arrangements with PLOS to administer payment for full publication fees for their institutions' authors. To be eligible, authors must be a corresponding author affiliated with the institution or agency in the Institutional Account Program (fully paid or restricted). *(Special note to UK authors — certain institutions will restrict payment to cover for Wellcome Trust and RCUK research grant recipients only)* Authors who need to request additional support should apply for PLOS PFA.
**IgG1 as a Potential Biomarker of Post-chemotherapeutic Relapse in Visceral Leishmaniasis, and Adaptation to a Rapid Diagnostic Test**

**Abstract**

**Background:** Visceral leishmaniasis (VL), caused by protozoa of the *Leishmania donovani* complex, is a widespread parasitic disease of great public health importance; without effective chemotherapy symptomatic VL is usually fatal. Distinction of asymptomatic carriage from progressive disease and the prediction of relapse following treatment are hampered by the lack of prognostic biomarkers for use at point of care.

**Methodology/Principal Findings:** All IgG subclass and IgG isotype antibody levels were determined using unpaired serum samples from Indian and Sudanese patients with differing clinical status of VL, which included pre-treatment active VL, post-treatment cured, post-treatment relapsed, and post kala-azar dermal leishmaniasis (PKDL), as well as seropositive (DAT and/ or rk39) endemic healthy controls (EHCs) and seronegative EHCs. *L. donovani* antigen-specific IgG1 levels were significantly elevated in relapsed versus cured VL patients (*p* < 0.0001). Using paired Indian VL sera, consistent with the known IgG1 half-life, IgG1 levels had not decreased significantly at day 30 after the start of treatment (*p* = 0.8304), but were dramatically decreased by 6 months compared to day 0 (*p* = 0.0032) or day 15 (*p* < 0.0001) after start of treatment. Similarly, Sudanese sera taken soon after treatment did not show a significant change in the IgG1 levels (*p* = 0.3939). Two prototype lateral flow immunochromatographic rapid diagnostic tests (RDTs) were developed to detect IgG1 levels following VL treatment: more than 80% of the relapsed VL patients were IgG1 positive; at least 80% of the cured VL patients were IgG1 negative (*p* < 0.0001).

**Conclusions/Significance:** Six months after treatment of active VL, elevated levels of specific IgG1 were associated with treatment failure and relapse, whereas no IgG1 or low levels were detected in cured VL patients. A lateral flow RDT was successfully developed to detect anti-*Leishmania* IgG1 as a potential biomarker of post-chemotherapeutic relapse.

**Introduction**

The leishmaniases are widespread neglected infectious diseases of major public health importance, caused by protozoan parasites of the *Leishmania (Leishmania)* and *Leishmania (Viannia)* subgenera. There are two principal symptomatic clinical presentations of leishmaniasis: a) visceral (kala-azar, VL) caused by the *Leishmania donovani* complex, with circa 400,000 cases per year [1], which without appropriate chemotherapy is usually fatal, and b) cutaneous (CL) caused by diverse *Leishmania* species, some of which may give rise to diffuse cutaneous leishmaniasis (DCL) or metastatic mucocutaneous disease (MCL), the latter with devastating destruction of the nasopharynx [2]. The effective clinical management, chemotherapy and control of transmission of VL are...
Author Summary

Visceral leishmaniasis (VL) is a systemic disease with highest prevalence in South Asia, East Africa, and Brazil. VL is caused by protozoan (unicellular) parasites of the *Leishmania donovani* complex, transmitted to humans when an infected sandfly takes a bloodmeal. Within the human host, the parasites replicate within cells, particularly of bone marrow and spleen. Without effective treatment, symptomatic VL is usually fatal. As outlined in a recent World Health Organisation report, the development of new diagnostic tools to test for successful cure after chemotherapy is a research priority. In this work we investigated the association of clinical status of VL patients (active pre-treatment, and those deemed cured or relapsed post-treatment) with subclasses of the IgG antibody response made to *L. donovani* infection. We show that high levels of subclass IgG1 are found in pre-treatment and relapsed patients, but are very much lower in patients deemed to be cured. We further show that the decrease in IgG1 is detectable in patients 6 months after successful treatment, and that this detection method can be adapted to a rapid diagnostic test format requiring minimal technical expertise. Thus we believe that IgG1 levels are potentially a biomarker of post-chemotherapeutic monitoring.

largely dependent on early and unequivocal diagnosis. Given that many VL patients live below the poverty threshold in remote areas poorly serviced by the health system, the diagnostic tools should be ASSURED (Affordable, Sensitive, Specific, User Friendly, Rapid, Equipment free and Deliverable where needed) [3]. The most sensitive and specific method to detect the causative agent of VL is microscopic examination of (invasive) spleen aspirates; bone marrow and lymph node aspirates provide similar high specificity but lesser sensitivity. More user-friendly point-of-care (POC) diagnostics have been developed based on antibody detection against rK39 and these provide high diagnostic accuracy in suspected first-time episodes of VL when combined with a clinical case definition [4–6]. However, these rapid diagnostic tests based on antibody detection are unable by themselves to distinguish asymptomatic carriers from those who will progress to acute fatal disease, and following chemotherapy they remain positive for many months precluding the detection of any relapse. To resolve the limitations of current diagnostic tools higher resolution, non-invasive, rapid and affordable POC tests are thus needed that define clinical status and indicate prognosis.

Current serological tests for VL include the enzyme linked immunosorbsent assay (ELISA) with either crude or purified *Leishmania* promastigote antigens, the direct agglutination test (DAT) or indirect immunofluorescence test (IFAT) [7,8]. Each of these tests has disadvantages: the ELISA requires laboratory facilities and technical training; the DAT test has limited commercial access and involves several hours or overnight incubation before reading the results, and the IFAT uses a costly fluorescence microscope.

The recombinant repetitive antigen rK39, a product of the *Leishmania* kinesin-like gene, which was first cloned from Brazilian *Leishmania infantum* (synonym *L. chagasi*) [9] has been adapted to an immunochromatographic, lateral flow format and applied extensively as a rapid diagnostic test (RDT) for VL. However, in multicentre trials rK39 had much higher sensitivity in South Asia than in East Africa [10,11]. This could be due to the geographical diversity in the 6.5 repeats within the rK39 antigen sequence [12] and/or regional differences in anti- *Leishmania* IgG titres between the different human populations [13]. A modified recombinant derivative of rK39, designated rK28, which incorporated the first two rK39 repeats of a Sudanese kinesin flanked by HASPB1 and HAPB2 repeats, improved serological sensitivity for East African VL patients [14]. The ELISA, DAT, IFAT, rK39 and rK28 serological tests all rely on the detection of anti- *L. donovani* complex IgG. In human VL, the IgG is produced secondarily, after IgM. IgG is divided into IgG1, IgG2, IgG3, and IgG4 subclasses, according to their ranked relative abundance in normal serum [15]. In general, human IgG1 and IgG3 are generated in response to protein antigens, whilst IgG2 and IgG4 are instead predominantly produced in response to polysaccharide antigens [15]. Previous studies on the humoral responses during active VL and after treatment, and on post kala-azar dermal leishmaniasis (PKDL), have been performed using samples from multiple endemic regions and a variety of serological tests [16–31]. Several of these studies, almost all of which used ELISAs, assessed anti- *L. donovani* complex titres of IgG, its subclasses and other Ig isotypes. In terms of IgG subclasses, increased IgG1 titres were identified in active disease (VL or PKDL) compared to healthy controls, and reduced IgG1 titres were reported after successful VL treatment. This published work suggested that the dynamics between proportionate IgG subclass responses and the clinical status of patients warranted further investigation to search for prognostic VL biomarkers.

A recent WHO report [8] designated the development of new diagnostics to determine cure as a research priority for VL, and there is an additional need for biomarkers to distinguish asymptomatic non-progressors from early progressive VL. Here we explore the potential of differential IgG subclass profiles to provide a biomarker for patients who relapsed after chemotherapy and therefore require urgent follow-up and life-saving additional or alternative chemotherapy. We show that the dynamics and levels of specific IgG1 responses can be indicative of relapse, and can be assessed using a simple, lateral flow immunochromatographic RDT format.

Methods

Ethics statement

In India, research on comparative serology and the collection of all serum or plasma samples was approved by the Ethics Committee of the Banaras Hindu University, Varanasi. Similarly, in Sudan research and collection of serum samples was approved by the Ethical Research Committee, Faculty of Medicine, University of Khartoum and the National Health Research Ethics Committee, Federal Ministry of Health. Written informed consent was obtained from all adult subjects included in the study or from the parents or guardians of individuals less than 18 years of age. This research was also approved, as part of the NIDIAG project, by the London School of Hygiene and Tropical Medicine Ethics Committee.

Sources of sera/plasma

Indian plasma samples were collected after 2007 from active VL, cured, relapsed, PKDL and asymptomatic groups from the endemic region of Muzaffarpur, Bihar state, north-eastern India, and control subjects from a region where VL is not endemic. In India active cases of VL were diagnosed parasitologically by microscopy of splenic aspirates. Sudanese serum samples were collected in 2011 and 2013, from active VL, treated, relapsed, PKDL, and endemic controls in the Gedaref region in eastern Sudan. All patients were HIV negative. Active cases of VL were diagnosed by a combination of microscopy of bone marrow or
lymph node aspirates in conjunction with serological assays. We have previously observed that serum and plasma derived from the same sample show no difference in titre in ELISA against *L. donovani* lysate (unpublished observations).

**Unpaired samples.** Table 1 shows the numbers of samples used in unpaired comparisons of IgG subclass responses and clinical status. For the Indian samples, two sets of comparisons were performed using these unpaired samples. There was an initial pilot study (Trial 1), followed by an expanded investigation (Trial 2), using different samples in each case. For the Sudanese sera, only one study was performed, after the Indian pilot serology.

**Paired samples and multiple sequential samples.** The comparative dynamics of IgG subclass response were studied using paired serum samples or, in the case of PKDL patients, several sequential samples from individual patients. Sera had been collected prospectively and the intervals between collections are shown in Table 2. For the Indian patients samples were available prior to treatment of active VL (day 0), paired with days 15, 30, or approximately 180 after start of treatment, depending on the patient. For Indian PKDL multiple sequential serum samples from the same patient were available at days 0, 30, 60, and 180 or 360 (Table 2). Paired sera from Sudanese patients were taken prior to treatment (day 0) and at the end of treatment lasting 11 days (ambisome), 17 days (sodium stibogluconate (SSG)+paromomycin) or 30 days (SSG alone).

**Antigen preparation**

*L. donovani* strain MHOM/IN/80/DD8 isolated from India, and MHOM/SD/97/LEM3458 isolated from Sudan, were cultured in αMEM (Sigma, UK) supplemented as described [32]. Mid-to-late log phase promastigote cultures were washed three times in phosphate-buffered saline (PBS), followed by three cycles of flash-freezing in liquid nitrogen and thawing in a 26°C water bath. Subsequently, these cells were subjected to three 30 seconds, 12-micron, sonication cycles on ice at 30 second intervals using a Soniprep 150 sonicator (MSE, UK). Sonicates were centrifuged at 12000 g for 1 minute at 4°C, and the supernatants were used as antigen. Protein concentrations in these lysates were determined using the BCA Protein Assay kit (Fisher Scientific, Loughborough, UK).

**ELISA**

Lysates of *L. donovani* DD8 (for Indian samples) or LEM3458 (for Sudanese samples), diluted to 2 μg/ml in 35 mM NaHCO₃/15 mM NaCO₃ buffer (pH 9.6), were added at 100 μl/well to Immulon 4HBX ELISA plates (VWR, Lutterworth, UK) and incubated overnight at 4°C. After washing the plates three times using PBS containing 0.05% (vol/vol) Tween 20 (Sigma, Gillingham, UK) (PBST), they were blocked using 200 μl/well PBSTM, containing 2% skimmed milk powder (Premier International Foods, Spalding, UK) at 37°C for 2 hr. Following three PBST washes, the human sera were added at 1:400 dilution for the Indian sera or 1:100 dilution for the Sudanese sera, in PBSTM, and the plates were incubated at 37°C for 1 hr. The different sample concentrations were used due to the significantly lower anti-*Leishmania* IgG response generated by the Sudanese VL patients, as recently described [13]. Following six PBST washes, 100 μl of horseradish peroxidase-conjugated subclass-specific mouse monoclonal antibodies specific for human IgG1 (ab99774), IgG2 (ab99784), IgG3 (ab99829) or IgG4 (ab99817) (Abcam, UK), diluted 1:5000 for the Indian sera or 1:1000 for the Sudanese sera, in PBSTM, were added and plates were incubated at 37°C for 1 hr.

Human IgG isotype responses were determined using 100 μl/well of a 1:5000 dilution for the Indian sera or 1:2500 dilution for the Sudanese sera, of horseradish peroxidase–conjugated donkey anti-human IgG secondary antibody (709-035-149: Jackson ImmunoResearch, West Grove, USA) with incubation at 37°C for 1 hr.

Following six PBST washes, 50 mM phosphate/citrate buffer (pH 5.0) containing 2 mM o-phenylenediamine HCl and 0.007% (vol/vol) H2O2 (Sigma, UK) was added at 100 μl/well and incubated in the dark at room temperature for 15 minutes. The substrate reactions were then stopped by the addition of 2M H2SO4 (50 μl/well) and the ELISA plates were read at 490 nm (Spectra Max 190, Molecular Devices, Sunnyvale, USA, or MRX II, Dynex Technologies, Chantilly, USA). These assays were performed on duplicate plates, simultaneously.

Statistical analyses

ELISAs cut-offs were determined by the mean values plus three standard deviations obtained from the seronegative endemic healthy control serum samples. Statistical analysis on ELISA data (2-tailed unpaired t-test for unpaired samples, and paired t-test for paired/sequential samples, with 95% confidence interval in both cases) was performed using GraphPad Prism version 4.02 for Windows (GraphPad Software, San Diego, California, USA).

Prototype L. donovani antigen-specific IgG1 immunochromatographic RDTs

The prototype lateral flow immunochromatographic tests consisted of a cassette with a nitrocellulose membrane, a sample pad, a conjugate pad and an absorbent pad, backed with a plastic strip. The nitrocellulose membranes were sensitized with crude L. donovani (strain LEM3458) antigen lysate produced as described above and anti-human IgG1-specific antibody labelled with colloidal gold was dried on the conjugate pad. This strip was housed in a plastic cassette with two windows: the application well and the test/reading window. Two prototypes of this assay were developed and tested. For prototype 1, 2 μl of serum and 2 μl of buffer were added to the nitrocellulose strip and then 90 μl of buffer was added to the application well. In prototype 2, the application of 2 μl of serum on the strip was followed by the addition of 75 μl of buffer in the application well. The human IgG that migrated over the nitrocellulose membrane reacted with the immobilized target antigens. The anti-human IgG1-specific conjugated MAb rehydrated by the buffer recognised the antigen-bound human IgG1 in the sample, thereby resulting in a red-purple coloured band. A control line ensured that the human IgG and conjugated anti-human IgG1 migration had occurred successfully. The prototype tests were used with sets of post-chemotherapeutic sera from Indian patients considered to have relapsed VL (n = 30 for prototype 1, of which 22 were also used with prototype 2) or cured VL (n = 21 for prototype 1, of which 5 were also used with prototype 2). Fisher’s exact 2-tailed test was used for testing the difference between proportions.

Results

The IgG1 subclass responses gave discrete separations between cured versus active VL and relapsed VL (Figure 1A and 1B). This potential human IgG1 subclass association with clinical VL status was therefore investigated further, in particular to determine whether it could be suitable for development as a rapid (lateral flow) diagnostic test (RDT) to detect relapsed VL patients at point of care (POC). IgG isotype responses showed a similar trend to IgG1; however as illustrated in Figure 2 (see below, paired
samples) and already noted in the literature [33–37] this was less apparent and was inconsistent.

In Indian VL IgG1 levels were high pre-treatment and in relapse but were negative or substantially diminished in cured VL patients.

Figure 1A and Table S1 show the results of the initial pilot study of IgG subclass in unpaired Indian VL patients with different clinical status. There was marked elevation of IgG1 levels in active (untreated) VL patients; IgG1 levels were dramatically reduced in patients who were treated and considered to be cured by clinical and parasitological assessments. Thus, 90.0% (18/20) pre-treatment active VL patients were serologically positive, above the cut-off value, whereas only 33.3% (7/22) patients considered to be cured remained positive, all of whom had low IgG1 titres (p< 0.0001, cured VL versus active or relapsed VL; Figure 1A). However, the IgG1 levels in the patients who were unsuccessfully treated were high and at levels comparable to the group of patients with active VL prior to treatment (p = 0.485; Figure 1A; Table S1). This trend for IgG1 levels was partially mirrored by IgG3. The IgG3 levels were however lower in the active VL patients (IgG1: 90.0% positive; IgG3: 75.0% positive) and the relapsed VL patients (IgG1: 84.2% positive; IgG3: 52.6% positive) patients and 47.4% (9/19) of these relapsed VL patients were IgG3 negative (Figure 1A; Table S1). In comparison IgG2 profiles were very weak (active VL: 5.0% positive; relapsed VL: 15.8% positive; cured VL: 0.0% positive) and IgG4 levels were negative or at the cut off boundary, except for one cured patient and one in the other disease group (a meningitis patient) (Figure 1A).

An expanded study of Indian VL confirmed that elevated IgG1 levels were a feature of relapse.

Based on the initial study showing that elevated IgG levels were a potential biomarker of Indian VL treatment failure and relapse, a larger number of unpaired samples from Indian VL patients were analysed, together with those from a post kala-azar dermal leishmaniasis (PKDL) group, and from a group of patients who were VL asymptomatic but all of whom had positive DAT and/or rK39 serology. Since this second larger cohort was investigated after the initial study (Trial 1), the results are presented separately in Figure 1B, but were also incorporated into Table S1. In Trial 2 similar results were obtained to those in Trial 1, with 67.4%, 71.4% and 3.6% of the active VL, relapsed VL and cured VL

(A) Indian VL pilot study (Trial 1). (B) Indian VL expanded study (Trial 2). (C) Sudanese VL. Mean and 95% CI are shown for each data set (solid black lines); note the different Y axis scales. In each study set, the means plus three standard deviations obtained using DAT-seronegative endemic healthy control (EHC) samples was used to calculate the cut-off value (dotted line) and p values of<0.05 were considered significant.

doi:10.1371/journal.pntd.0003273.g001

Figure 1. Specific IgG1 ELISA levels were high in active and relapsed VL but negative or substantially decreased in cured VL using unpaired serum samples. [A] Indian VL pilot study (Trial 1). [B] Indian VL expanded study (Trial 2). [C] Sudanese VL. Mean and 95% CI are shown for each data set (solid black lines); note the different Y axis scales. In each study set, the means plus three standard deviations obtained using DAT-seronegative endemic healthy control (EHC) samples was used to calculate the cut-off value (dotted line) and p values of<0.05 were considered significant.
patients, respectively, being IgG1 positive (Figure 1B, Table S1). A lower percentage of the cured VL patients were IgG1 positive in Trial 2 compared to Trial 1 (Trial 1: 33.3% positive; Trial 2: 3.6% positive), although the absolute readings for Trial 1 cured were low and adjacent to cut-off borderline. IgG1 detection showed a much greater sensitivity and specificity than IgG3. Thus amongst the four IgG subclasses IgG1 was indicated for potentially identifying VL Indian patients with relapse versus cure after chemotherapy.

Sudanese VL patients had reduced IgG1 levels after treatment

Comparisons of Sudanese VL IgG subclass responses were performed with unpaired sera from active VL, treated VL and PKDL patients, as well as DAT-positive and DAT–negative endemic healthy controls (Table S1), at 1:100 dilution to allow for the overall lower IgG titres of Sudanese VL sera compared to Indian sera [13]. A slightly lower percentage of the Sudanese active VL patients (57.4%) had positive specific IgG1 levels compared to the Indian patients (Trial 1: 90.0%; Trial 2: 67.4%), but the treated Sudanese VL patients had low positive IgG1 levels (4.6%) similar to the cured VL patients in the Indian Trial 2 (3.6%). Thus the IgG1 levels in Sudanese active VL and Sudanese treated VL were significantly different (p<0.0001; Figure 1C, Table S1).

Anti-L. donovani IgG1 levels were raised in Indian PKDL

IgG1 levels were elevated in Indian PKDL compared to cured patients. Positivity rate was higher in Indian PKDL (Trial 2, 45.8%) than in Sudanese PKDL (4.3%), (Figures 1B and 1C, Table S1), although overall antibody levels in Sudanese VL were also lower, as we have reported previously [13].

In Indian VL, anti-L. donovani specific IgG1 levels decreased in paired samples approximately 6 months after successful treatment

Having determined that specific IgG1 levels were elevated in single serum samples from cases of VL treatment failure but were decreased in cured VL patients, we compared, for single individuals, paired serum samples obtained prior to or at start of

Figure 2. IgG1 decrease following cured VL became more significant with time. [A] Indian paired samples group 1, day 0 and 30. [B] Indian paired samples group 2, day 0 and 180. [C] Indian paired samples group 3, day 15 and 180. [D] Sudanese paired samples, day 0 and after treatment lasting 11, 17 or 30 days. Empty and filled columns represent the earlier and later samples of each pair respectively. Comparison of column heights allows the change in IgG1 level to be seen for each individual patient pre- and post-chemotherapy. For each data set represented in [A]–[D], paired samples from individual patients are presented in the main graph, and in the insets the mean and 95% CI compiled from all patients in that data set are shown for both IgG1 and IgG isotype. Mean plus three standard deviations of the results obtained using the seronegative endemic healthy control samples was used to calculate each cut-off value (dotted line) and p values of<0.05 were considered significant (subclasses IgG2–4 were also assayed but were not informative). doi:10.1371/journal.pntd.0003273.g002
treatment and again at subsequent particular times. As shown in Table 2, for Indian VL paired samples from three Indian VL groups were analysed: group 1: day 0 and 30, group 2: day 0 and 180 and group 3: day 15 and 180. 

In Sudanese VL specific IgG1 levels did not fall immediately after the start of treatment. Assay of IgG1 levels with paired samples from treated Sudanese VL patients (day 0 and 11, 17 or 30) showed that IgG1 subclass responses do not fall precipitously immediately after start of treatment (Figure 2D), as with Indian VL patients, which also showed no rapid fall in IgG1 level shortly after start of treatment (Figure 2A). However, with one exception, in which titre increased (patient 16, Figure 2D) all Sudanese VL patients showed a non-significant trend for titre to decrease slightly.

Prototype immunochromatographic rapid diagnostic tests could detect specific IgG1 levels indicative of relapsed VL

Two prototype immunochromatographic (lateral flow) RDTs were designed (see Methods) and tested to determine whether they could be used to discriminate between relapsed and cured VL patients by the detection of L. donovani antigen-specific IgG1 levels. The results for some of these patients are shown in Figure 3. As summarised in Table 3, most of the serum samples provided clear positive IgG1 results for the relapsed VL patients. Thus with prototype 1, 25 of 30 (83.3%) relapsed VL patients were positive but only 4 of 21 (19.0%) cured VL patients. Similarly, with prototype 2, 19 of 23 (82.6%) relapsed VL patients were positive but only 1 of 5 (20%) cured patients (p < 0.0001 for the prototypes 1 and 2 cumulative results, Fisher’s exact 2-tailed test). None of these 5 cured patients tested with either prototype 1 or 2 gave strong positive IgG1 signals. One of patients with malaria and no diagnosed VL had detectable IgG1. Thus, these prototype L. donovani antigen-specific IgG1 lateral flow assays could clearly discriminate between most of the relapsed and cured VL patients.

Discussion

Diagnosis of VL is not straightforward: clinical symptoms may overlap with other infectious diseases associated with fever syndrome; parasitological methods of diagnosis are invasive and have limited sensitivities. The currently recommended rK39-based rapid diagnostic tests have their limitations as they cannot distinguish systematically and reliably between the different clinical phases of VL. A large Indian/Nepalese population study reported an association between higher DAT and/or rK39 titres and risk of progression from asymptomatic to symptomatic VL [38]. Recent papers have studied asymptomatic (seropositive) populations in Bangladesh [39] and elsewhere [40–42]. In Bangladesh when assessing a patient cohort at 24 months follow-up for VL disease development, discrepancies were found between the molecular and serological tests [39]. In one long-term follow-up of 55 rK39 seropositive asymptomatic cases in India 69% developed VL and 31% remained asymptomatic [43]. However, the proportion of L. donovani complex seropositive asymptomatic individuals that progresses to symptomatic VL can be minor, and varies between endemic regions, for example between 1: 2.4 in Sudan [44], 4:1 in Kenya [45], 8:1 in Brazil [46], 4:1 in Bangladesh [47], 8:9:1 in India and Nepal [48], and 50:1 in Spain [49]. There is no rapid diagnostic test that determines which asymptomatic carriers will progress to active VL. Nor is there a rapid diagnostic test that is a biomarker of treatment failure and relapse as opposed to cure after chemotherapy. Thus development of such point of care tests has been identified by WHO as a research priority [8].

We are by no means the first to investigate the dynamics of antibody response in the different clinical phases and evolution of VL. The persistence of detectable anti-Leishmania IgG years after treatment, mainly using DAT and rK39, has been reported from India [33,34], Brazil [35], and Sudan [36,37]. We are not the first to mention that IgG subclass profiles may be associated with clinical status. The evaluation of IgG subclasses has been applied in other parasitic infections including echinococcosis [50–52], toxoplasmosis [53,54], and malaria [55–57]. Table 4 summarises
IgG1 as a Biomarker in VL

We have not performed a western blot analysis with sera taken at different time points after treatment to determine whether the decrease in IgG1 titres relates to response to particular *L. donovani* antigens. However, one published study comparing western blot profiles using subclass specific conjugates and sera taken before and after treatment reported a general decline in band recognition and not the selective disappearance of bands [26]. Here we have used antigen derived from cultured promastigotes. However, in human VL the stage of the *Leishmania* life cycle is the amastigote, and given access to sufficient quantity of amastigote antigens it would be worthwhile to repeat such a comparative western blot study with amastigotes and subclass specific conjugates. In this way it might be possible to identify and subsequently isolate a specific amastigote antigen(s) applicable to determination of cure.

Recently decreases in IgG1 and IgG3 after cure [59] or post-active disease scarring [60] have also been reported for Brazilian cutaneous leishmaniasis (CL), and higher levels of these IgG subclasses in Turkish patients with active CL compared to endemic controls [61].

IgG subclass responses have been reported for experimental murine models of *Leishmania* infection and for canine infections with *L. infantum*, based on FcγR binding [62]. For canine leishmaniasis there are conflicting interpretations of IgG subclass profiles, (reviewed in [63]), reportedly due to confusion in subclass nomenclature of the commercial polyclonals used [63,64]. A recent study has proposed improvement of comparative studies by categorising canine IgG subclasses against function of their human analogues [65].

The detection of VL relapse following unsuccessful chemotherapy is of special importance because without effective treatment symptomatic VL is considered to be almost invariably fatal. Thus, if relapse is not recognized and followed up with repeated or alternative treatment, patients, who are often relatively isolated in rural endemic regions, will succumb to the disease. We were therefore interested to examine the IgG subclass profiles in unsuccessful treatment and relapse. Notably, IgG1 levels were raised in patients who failed to respond to chemotherapy and were considered to have relapsed 6 months after start of treatment. As in active VL the majority of relapsed patients had IgG1 titres clearly above the ELISA cut-off (Figures 1A and 1B). Such elevation of IgG1 in patients not responding to treatment has been mentioned rarely in the literature [21,23]. Accordingly, to provide an RDT for point of care application we devised two lateral flow

patients might be screened/rescreened for HIV infection to assess IgG1 might be influenced by the pre-treatment titre. All relapse treatment, since despite successful treatment, extent of decline of patients, ideally with baseline application of the RDT prior to (longitudinal study (since some patients may relapse between 6 months and one year after treatment [66]) and a larger cohort of patients, ideally with baseline application of the RDT prior to treatment, since despite successful treatment, extent of decline of IgG1 might be influenced by the pre-treatment titre. All relapse patients might be screened/rescreened for HIV infection to assess whether relapse may be associated with immunocompromised status. Thus, with optimisation and standardisation of reagents, and preferably with higher discriminative sensitivity, this RDT may provide an important and life-saving epidemiological tool to detect relapse of VL.

We have shown the potential of IgG1 to be a simple indicator of VL clinical status in terms of relapse. Symptomatic VL is treated at an acute phase of infection, which may favour the decline of IgG1 seropositivity in cure; it remains to be seen whether such markers are equally applicable to the treatment of prolonged chronic infections. As PKDL is a long-established chronic infection, this may explain why IgG1 does not decline with time after chemotherapy. A recent study has proposed that a high seropositivity in asymptomatic people may be associated with greater risk of progression to symptomatic VL [38]. Further work

prototypes, with which we assessed IgG1 seropositivity in treatment failure and relapse. Although we had already demonstrated that IgG1 levels were drastically reduced in cure, 6 months after treatment, for comparison we included a set of serum samples from such cured patients. Strikingly, the majority of patients considered to have relapsed were strongly positive in the IgG1 specific RDT, whereas none of the cured patients were strongly positive and the vast majority were entirely negative (Table 3, Figure 5). Further validation is indicated with a one year follow-up on those cured patients (n = 7) gave similar but less intense western blotting banding patterns.
could investigate whether high anti-*L. donovani* IgG1 titre in asymptomatic patients is a potential biomarker for progression to active VL.

Seroepidemiological comparisons with more detailed and sophisticated technological analysis of patient profiles is clearly a promising approach to defining precise, robust and widely applicable biomarkers.

Based on analysis and interpretation of our results, in conjunction with review of the relevant literature, we conclude that:

1. Retention of high anti-*L. donovani* IgG1 titre (or presumably rising titre) 6 months after chemotherapy (but not immediately after chemotherapy) is an indicator of treatment failure and relapse (however this is not likely to hold true for immunocompromised HIV co-infected patients, in whom antibody responses may be impeded). Patients with such a serological profile require follow-up and alternative treatment or will almost certainly succumb to fatal VL.

2. Most importantly we have shown that high anti-*L. donovani* IgG1 levels 6 months after treatment, and in comparison with preceding pre- or shortly post-treatment levels, are amenable to detection with a simple lateral flow POC applicable RDT.

Nevertheless, such RDTs should not be applied at the exclusion of concomitant clinical evaluation.

Further investigation of seroepidemiological indicators is clearly justified to find even better alternative biomarkers of clinical status, in particular to identify asymptomatic progressors to VL, as well as to distinguish cure from treatment failure and relapse.

6. GENERAL DISCUSSION: RECAPITULATION AND FUTURE PERSPECTIVES

6.1 Trypanosoma cruzi and Chagas disease

From the first demonstration of the diversity of *T. cruzi* in naturally occurring cycles (Miles *et al.*, 1977), the relevance to differing clinical and geographical presentations has been the subject of enquiry (Miles *et al.*, 1981). Lineage identification, which was initially based on MLEE and then genotyping, requires that the parasite is first isolated. This is challenging in the post-acute phase of disease, due to the low parasitaemia, and confounded by the tissue tropisms of different lineages. Thus, the indirect approach of identifying serologically antibodies produced against lineage-specific antigens has been applied here.

In this project, the *T. cruzi* surface mucin TSSA, previously described as being expressed on the bloodstream form of the parasite and exhibit sequence dimorphism (Di Noia *et al.*, 2002), has been further investigated (ANNEX 1). By sequencing the part of the TSSA coding region containing the previously-described amino acid diversity from genomic DNA of isolates representing TcI-TcVI and spanning the geographical and ecological range of *T. cruzi*, a greater degree of TSSA diversity was identified. Specifically, the sequence reported as being restricted to isolates described grossly as ‘TcII’ (now called TcII-TcVI in subsequently revised nomenclature) was found only in TcII, TcV, and TcVI. In addition, TcV and TcVI also contained an alternate haplotype which differs by the substitution of an alanine residue in place of threonine. TcIII and TcIV were also both discovered to have their own lineage-specific sequences, not previously identified. The TSSA sequence of TcI was found to be as previously reported (ANNEX 1: Figure 3).

Peptides based on these lineage-specific sequences were synthesised and used in this project in ELISA with serum from chagasic patients from a range of endemic countries in order to identify lineage-specific serological reactions (ANNEX 2). The use of recombinant, *E. coli* produced TSSA fusion proteins has been reported before (ANNEX 2: Table 3). In those studies, the TSSA sequences of the proteins contained not only the polymorphic region (residues 39-51), but also up to 26 of the flanking amino acids, which are highly conserved between *T. cruzi* lineages; however, this project is the first report of the use of synthetic peptides in this way. Here, recognition of the TSSApep-II/V/VI common peptide and
TSSApep-V/VI was very commonly found in serum originating from the Southern Cone countries (Brazil, Bolivia, Argentina), in agreement with their prevalence in this region based on MLEE/genotyping of parasite isolates. An unexpected finding was that 4/20 sera from Ecuador also reacted with TSSApep-II/V/VI, as these lineages had not previously been reported from that country. Another novel finding was the serological identification of TSSApep-IV, by one sample each from Colombia and Venezuela. However TSSApep-I, despite the broad geographical distribution of this lineage, was recognised only very rarely by the sera (ANNEX 2: Table 1 & Figure 3). The Colombian samples used here were the same as those used by Risso et al. (2011), in which western blotting of recombinant TSSA-II identified an unexpectedly high level of reactivity against this lineage north of the Amazon, including Colombia; however in this study, no such reactions were seen against the corresponding peptide TSSApep-II/V/VI.

Associations between peptide recognition and clinical symptoms were also investigated. Among the Brazilian patients, a much higher proportion of TSSApep-II/V/VI responders had ECG abnormalities than non-responders (38% vs. 17%, p<0.0001).

A novel bioinformatic analysis of the TSSA sequences from which these peptides derive predicted that TSSApep-II/V/VI and TSSApep-V/VI contain sequences of high antigenicity, whereas the TSSApep-I sequence predicts low antigenicity (ANNEX 2: Figure 4).

Thus this project has demonstrated that the greater polymorphism of the TSSA gene can be exploited in ELISA by using synthetic peptides based on this diversity, to identify an individual’s history of lineage infection, association with clinical presentation, and geographical distribution of lineages.

Future perspectives & ongoing work:

Identification of a TcI-specific peptide: For unknown reasons, the TSSA peptide specific for TcI serology has not been successful in this project, even with those samples previously genotyped as containing TcI isolates, or presumed to do so due to geographical origin. Thus, identification of a robust TcI-specific peptide remains a crucial goal in sero-epidemiological studies of Chagas disease. The approaches to achieve this include using in
silico bioinformatic analyses on reference genomes to identify candidate proteins displaying desirable antigenic properties, and the use of genomic or synthetic peptide libraries in differential screening of Tcl and TcII sera (natural or experimental).

Expanded studies of lineage identification and clinical symptoms: The link between infecting *T. cruzi* lineage(s) with the broad range of clinical symptoms remains largely circumstantial, with a paucity of candidate parasite or human factors identified. The application of lineage-specific serology to identify an individual’s history of lineage infection would be a great aid in associating lineage to symptoms, and also potentially to act as a prognostic tool. This would require an expanded study of the type presented here (ANNEX 2), using samples from clinically well-characterised patients.

Adaptation to a lateral flow rapid test: TSSApep-II/V/VI, and to a lesser extent TSSApep-V/VI, have been shown here to be well recognised in the ELISA format for lineage-specific serology. A future and novel direction could be the incorporation of peptide(s) to a lateral flow, immunochromatographic, rapid diagnostic cassette, as described in Figures 13 and 32. This could be designed for use at point-of-care or in a research context, and also relevant for immunological surveillance of reservoir hosts (see following point).

Application to silvatic mammalian hosts: *T. cruzi* lineages circulate in the silvatic cycle by triatomine bugs feeding on mammal hosts. As with humans, lineage identification relies on parasite isolation and genotyping. The application of the lineage-specific serology described in this project would therefore have enormous potential in more fully understanding the ecology of lineages, particularly those which have been most associated with human disease. The use of TSSA (and future identified) lineage peptides, along with suitable host species-specific secondary antibodies, is envisaged to pursue this research direction.
6.2 *Leishmania donovani* and visceral leishmaniasis

Full-blown systemic, symptomatic VL is a gravely serious disease, which is almost always fatal without treatment. Accurate and timely diagnosis of infection with *L. donovani* complex is therefore of crucial importance in disease management. As shown in Tables 5 & 6, a significant difference in the sensitivity of the rK39 RDT between South Asia and East Africa had been previously identified. In this project, reasons potentially underlying this differential sensitivity were identified. These were parasite factors, namely the nature and extent of antigen diversity in the region coding for the 6.5 x 39 aa repeats used in rK39, and also human factors, namely the difference in overall anti-*Leishmania* IgG levels between VL patients from different endemic areas. Additionally, the nature of the IgG subclass response in VL patients of different status was analysed here.

This region coding for the 6.5 x 39 aa repeats used in rK39 was amplified and sequenced from a panel of East African *L. donovani* strains, and compared to published sequences (ANNEX 3). As expected from the fact that one of the PCR primers binds within a repeat region, multiple amplicons 117 bp apart were produced (ANNEX 3: Figure 2). On sequencing of the amplicon corresponding to 6.5 x 39 aa repeats from these strains, a wide range of polymorphism was found, including non-conservative charge changes, with the capacity to affect epitope structure and nature. In comparison with the sequence of rK39 and other published sequences mainly from South Asia, continent-specific polymorphisms were also identified (ANNEX 3: Figure 3). A similar approach to the proposed diagnostic antigen HASPB also revealed non-canonical combinations of repeat arrangements (ANNEX 3: Table 4).

As an alternative explanation for the lower sensitivity of rK39 RDT in East Africa, this project also analysed the role of anti-*Leishmania* IgG levels in VL patients from different endemic regions. These were Gedaref in Sudan and Bihar in India. Plasma samples from VL patients from both regions were reacted on the same ELISA plate coated with lysate antigen from both Indian and Sudanese *L. donovani* strains (ANNEX 4: Figure 1). Results were striking, with a significantly lower IgG response seen among Sudanese than Indian VL patients (p<0.0001). This was observed regardless of antigen source, age or gender of
patient (ANNEX 4: Figures 2&3). The lower IgG responses in the Sudanese cohort may be due to genetic, nutritional, or other factors.

In a WHO/TDR document (WHO, 2010e), case definitions for treatment outcome for VL patients were based on clinical and parasitological signs (Table 8), with another recent WHO publication listing an established marker of cure in VL as a knowledge gap and research priority (WHO, 2012). In this project, the discriminatory potential of IgG subclass responses in VL patients of differing clinical status by ELISA was evaluated (ANNEX 5). The clearest finding was the stark contrast in IgG1 levels comparing active (pre-treatment samples) plus those deemed to be therapeutically relapsed, versus those deemed to be therapeutically cured. The former group had displayed significantly elevated IgG1 levels compared to the latter (p<0.0001 for all cohorts of unpaired Indian and Sudanese samples; ANNEX 4: Figure 1). In accordance with the findings from the comparison of Sudanese and Indian overall anti-Leishmania IgG responses (Annex 4), the absolute values for the Sudanese IgG1 reactors were lower than for Indian. When performing the IgG1 ELISA on paired samples from the same patient before and either soon after or approximately 6 months after start of successful therapy, the IgG1 decrease in cured patients was manifest at the later time point when compared to the paired baseline samples (ANNEX 5: Figure 2). Following these findings, prototype immunochromatographic rapid tests to specifically detect IgG1 responses in VL patients were developed in collaboration with Coris BioConcept. Early results encourage the further, expanded evaluation of this test (ANNEX 5: Table 3 & Figure 3).

Future perspectives & ongoing work:

An expanded survey of the use of the IgG1 RDT: Following the encouraging early results on the utility of the prototype IgG1 RDT, it is envisaged to expand this to a larger set of samples, particularly paired samples of pre- and post therapy, those deemed to be either cured or relapsed. The RDT is also envisaged to be applied to asymptomatic patients who later progressed to symptomatic VL or remained as non-progressors, to investigate the utility of the IgG1 RDT as a tool for predicting disease progression, or more speculatively, on
the role of asymptomatic people in transmission to sandflies. The identification of further serological biomarkers is also encouraged by these results.

Identification of a *Leishmania* antigen indicative of current infection: Currently, non-parasitological diagnosis of VL depends on detection of anti-*Leishmania* IgG produced by the patient. The identification of *Leishmania* antigen(s) produced and excreted in the urine would be a non-invasive alternative for diagnosing active infection. An approach to this, as initiated by T Marlais, LSHTM, would involve the isolation of experimentally-derived anti-*Leishmania* IgG from immunised animals, and the subsequent generation of an anti-*Leishmania* IgG affinity column. After immunodepletion to remove common human urinary proteins from VL patients, any ligands which bound to the column would be eluted for analysis by mass spectroscopy to identify *Leishmania* protein fragments. Synthetic peptides or recombinant proteins derived from the parent molecules could then provide a basis for developing new serological or antigen capture assays.

### 6.3 Summary of overarching themes

This project has sought to analyse parasite diversity and improve serology for Chagas disease and visceral leishmaniasis. Both diseases are caused by protozoa of the order Kinetoplastida, family Trypanosomatidae, which share a number of morphological and molecular biological characteristics, but disparate modes of transmission and clinical disease. Consequently, they have been considered separately. Nevertheless, there are certain common themes.

Molecular analysis of antigen diversity: Exploitation of *T. cruzi* TSSA diversity allows a deeper investigation of an individual’s history of lineage infection, association with clinical symptoms, and geographical distribution. A similar approach to the *Leishmania* kinesin-like protein, a fragment of which is used as the rapid diagnostic antigen rK39, also revealed a great degree of diversity. However for VL, this diversity is predicted to disrupt the efficacy of serology using this antigen.

Diagnostic serology: In both Chagas disease and VL, a key research need identified by WHO is the development of biomarkers for disease status, as prognostic indicators or for monitoring treatment outcome. The research here has shown that elevated IgG1 levels in VL are associated with active disease or post-therapy relapse; subsequently, a similar serological survey of IgG subclass levels in Chagas disease was initiated. Early results, which
have not been included here, indicate that further investigations of these biomarkers in chagasic sera are also warranted.

Overall, for both T. cruzi and L. donovani, and for the serological reactions generated in their infected hosts, these results have shown the potential of deeper analyses to yield novel data and refined high resolution diagnostic and prognostic RDTs.
7. SUMMARY OF KEY FINDINGS

Trypanosoma cruzi and Chagas disease

- Greater genetic and amino acid diversity in the Trypanosoma cruzi surface mucin TSSA was revealed than had previously been reported, leading to the identification of lineage-specific epitopes [ANNEX 1 Bhattacharyya et al., 2010].
- Synthetic peptides based on TSSA diversity have been used to identify lineage-specific serological responses in chagasic patient sera, and for associating lineage-specific reactions with geographical distributions and clinical symptoms [ANNEX 2 Bhattacharyya et al., 2014].

Leishmania donovani and visceral leishmaniasis

- A greater diversity in the Leishmania donovani diagnostic antigens rk39 and HASPB sequences has been demonstrated, with ample scope for affecting their diagnostic antigenicity. [ANNEX 3 Bhattacharyya et al., 2013].
- Comparative serology has shown that a Sudanese VL patient cohort generated a significantly weaker anti-Leishmania IgG response than a corresponding Indian cohort, revealing a possible cause of the differential RDT sensitivity in different geographical regions [ANNEX 4 Bhattacharyya et al., 2014].
- IgG1 levels were found to be elevated in active and relapsed VL patients, but substantially diminished in cured patients, over the course of several months post-therapy, and identification of this biomarker can be achieved by a novel prototype RDT [ANNEX 5 Bhattacharyya et al., 2014].

APPENDIX

A.1 ChagasEpiNet Extracted from www.ki.se/chagasepinet/

“ChagasEpiNet is a European Union Seventh Framework Program funded project whose aim is to elucidate the epidemiology of the genetic lineages of Trypanosoma cruzi for improved understanding and prevention of Chagas disease. This project unites compatible research skills across 15 partner institutions in Europe and South America to study the disease in different endemic areas.

- Improve and standardise techniques for genotyping T. cruzi.
- Improve our understanding of the population genetics of T. cruzi
- Sequence the genome of T. cruzi lineage I.
- Develop lineage specific immunological diagnosis.
- Pilot studies to evaluate T. cruzi lineage specific associations with 1) Clinical outcome; 2) Congenital infection; 3) Cellular infectivity; & 4) Susceptibility to trypanocidal drugs.”

A.2 NIDIAG Extracted from www.nidiag.org

“NIDIAG is a European research network (Collaborative Project) coordinated by the Institute of Tropical Medicine. Our consortium brings together 13 complementary partners, including 2 private companies and 11 laboratories, from 4 European Member States and Associated Countries, 4 countries in Asia and 3 countries in Africa. The project is supported by the European Commission under the Health Priority of the 7th Framework Programme. The aim of the NIDIAG project is improve the quality of NID care at primary health care level in resource-poor settings. The major objectives of the NIDIAG consortium are: to develop and validate an integrated syndromic approach based on diagnosis treatment algorithms for three NID-related clinical syndromes frequently encountered in primary care settings,
namely the persistent fever syndrome (at least 2 week duration), the neurological syndrome, and the intestinal syndrome; to develop novel diagnostic platforms/assays tailored to specific epidemiological contexts at primary care level in NID-endemic settings.”

A.8 Cell culture reagents

A.8.1 T. cruzi

Stock solutions

- 1M HEPES: 23.8g/100 ml H₂O, pH 7.2
- Tryptone/trypticase: 17.5g/100 ml H₂O
- Haemin: 250mg/100 ml 0.01M NaOH
- PGAB: Final 100x stock
  - Na Glutamate: 2 mM, 3.4g/100 ml
  - Na Pyruvate: 2 mM, 2.2g/100 ml
  - Gentamycin: 50 μg/ml, 500 mg/ml

To 500ml RPMI 1640, add 50ml heat-inactivated FBS.

Combine in a 50ml tube the stock solutions:
- 10 ml HEPES
- 14 ml Tryptone
- 4 ml Haemin
- 6 ml PGAB

Filter this mix through a 0.2 μm filter directly into the RPMI/FBS. Store at 4°C.
A.8.2 *Leishmania*

αMEM

i) To 800ml ddH$_2$O in a 1 L bottle or beaker, dissolve:

<table>
<thead>
<tr>
<th>Component</th>
<th>Amount</th>
<th>conc.</th>
</tr>
</thead>
<tbody>
<tr>
<td>aMEM powder</td>
<td>1 bottle</td>
<td>(1x)</td>
</tr>
<tr>
<td>NaHCO$_3$</td>
<td>2.2g</td>
<td>(26.2 mM)</td>
</tr>
<tr>
<td>L-glutamine</td>
<td>0.59g</td>
<td>(4 mM)</td>
</tr>
<tr>
<td>D-glucose</td>
<td>3g</td>
<td>(16.7 mM)</td>
</tr>
<tr>
<td>HEPES</td>
<td>10g</td>
<td>(42 mM)</td>
</tr>
</tbody>
</table>

Adjust pH to ~7.5. Add ddH$_2$O to 860 ml.

ii) Prepare:

<table>
<thead>
<tr>
<th>Component</th>
<th>Amount</th>
<th>conc.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Haemin</td>
<td>5mg/50 μl 1N NaOH / 9.95 ml dH$_2$O</td>
<td>(0.008 mM)</td>
</tr>
<tr>
<td>Adenine</td>
<td>40 mg/500 μl 1N NaOH / 9.50 ml dH$_2$O</td>
<td>(0.3 mM)</td>
</tr>
<tr>
<td>Folic acid</td>
<td>5mg/40 μl 1N NaOH / 9.96 ml dH$_2$O</td>
<td>(0.011 mM)</td>
</tr>
<tr>
<td>D-biotin</td>
<td>2mg/100 μl 1N NaOH / 9.90 ml dH$_2$O</td>
<td>(0.008 mM)</td>
</tr>
</tbody>
</table>

iii) Transfer αMEM made to this point into a clean 1L bottle. In a cell culture cabinet, add:

<table>
<thead>
<tr>
<th>Component</th>
<th>Amount</th>
<th>conc.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Haemin, Adenine, Folic acid, D-biotin solutions; gentamycin</td>
<td>1 ml</td>
<td>(50 ug/ml)</td>
</tr>
</tbody>
</table>

iv) Sterile filter into an autoclaved 1 L bottle, using a bottle-top filter and vacuum pump.

v) Add

<table>
<thead>
<tr>
<th>Component</th>
<th>Amount</th>
<th>conc.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Foetal Calf serum (heat inactivated)</td>
<td>100 ml</td>
<td>(10%)</td>
</tr>
</tbody>
</table>

vi) Store at 4 °C.
