Abstract

Objective: Grey matter (GM) atrophy occurs in all multiple sclerosis (MS) phenotypes. We investigated whether there is a spatiotemporal pattern of GM atrophy that is associated with faster disability accumulation in MS.

Methods: We analysed 3,604 brain high-resolution T1-weighted MRI scans from 1,417 participants: 1,214 MS patients (253 clinically-isolated syndrome[ CIS], 708 relapsing-remitting[ RRMS], 128 secondary-progressive[ SPMS], 125 primary-progressive[ PPMS]), over an average follow-up of 2.41 years (standard deviation[ SD]=1.97), and 203 healthy controls (HCs) [average follow-up=1.83 year, SD=1.77], attending 7 European centres. Disability was assessed with the Expanded-Disability Status Scale (EDSS). We obtained volumes of the deep GM (DGM), temporal, frontal, parietal, occipital and cerebellar GM, brainstem and cerebral white matter. Hierarchical mixed-models assessed annual percentage rate of regional tissue loss and identified regional volumes associated with time-to-EDSS progression.

Results: SPMS showed the lowest baseline volumes of cortical GM and DGM. Of all baseline regional volumes, only that of the DGM predicted time-to-EDSS progression (hazard ratio=0.73, 95% CIs 0.65, 0.82; p<0.001): for every standard deviation decrease in baseline DGM volume, the risk of presenting a shorter time to EDSS worsening during follow-up increased by 27%. Of all longitudinal measures, DGM showed the fastest annual rate of atrophy, which was faster in SPMS (-1.45%), PPMS (-1.66%), and RRMS (-1.34%) than CIS (-0.88%) and HCs (-0.94%)[p<0.01]. The rate of temporal GM atrophy in SPMS (-1.21%) was significantly faster than RRMS (-0.76%), CIS (-0.75%), and HCs (-0.51%). Similarly, the rate of parietal GM atrophy in SPMS (-1.24-%) was faster than CIS (-0.63%) and HCs (-0.23%) (all p values <0.05). Only the atrophy rate in DGM in patients was significantly associated with disability accumulation (beta=0.04, p<0.001).
**Interpretation:** This large multi-centre and longitudinal study shows that DGM volume loss drives disability accumulation in MS, and that temporal cortical GM shows accelerated atrophy in SPMS than RRMS. The difference in regional GM atrophy development between phenotypes needs to be taken into account when evaluating treatment effect of therapeutic interventions.
Introduction

The clinical course of multiple sclerosis (MS) is heterogeneous. Some patients experience relapses with recovery (relapsing-remitting [RR] MS), while others develop progressive disability either from the onset (primary-progressive [PP] MS), or after a period of relapses (secondary-progressive [SP] MS). RRMS patients account for approximately 90% of cases at onset\(^1\), whose majority later progress to SPMS. The pathogenic mechanisms driving accrual of disability are beginning to be elucidated\(^2\): neurodegeneration plays a crucial role in determining accrual of disability over time\(^3\).

Neurodegeneration is reflected *in-vivo* by reduced brain volume (or brain atrophy), which can be measured by MRI\(^3\). Over time, brain volume declines more rapidly in MS patients when compared with age-matched healthy controls (HCs)\(^3\)–\(^6\). Across MS phenotypes, SPMS shows the fastest annual rate of brain atrophy, which is estimated to be 0.6% (compared to about 0.2% in age-matched HCs)\(^5\). The role of brain atrophy in monitoring response to treatments in MS is evolving: whole brain atrophy has been recently used as primary outcome measure in Phase II clinical trials in SPMS\(^7,8\).

Whole brain atrophy is mainly driven by neuroaxonal loss in the GM\(^3\). GM volume loss is associated with long-term disability\(^9,10\), and explains physical disability better than white matter\(^9,11\) and whole brain atrophy\(^5\). Some GM regions, such as the cingulate cortex and thalamus, are affected by volume loss more extensively than others\(^12,13\), and the extent of their volume loss correlates with disability\(^13,14\), and cognitive impairment\(^15\). Regional predilection for atrophy is not unique to MS; for example, hippocampal atrophy is more pronounced than the whole brain atrophy in the early phase of Alzheimer’s disease\(^16\). Although cross-sectional studies have previously shown patterns of regional atrophy in
different types of MS\textsuperscript{12,17}, studies on longitudinal evolution of atrophy in different structures across MS phenotypes are scarce.

The overarching goal of our study was to investigate whether there is a spatiotemporal pattern of GM atrophy that is associated with faster disability accumulation in MS. In a large multi-centre cohort, which included all MS phenotypes and HCs, we tested the following hypotheses: (i) some GM regions show faster atrophy rate than others and their rate may differ between MS phenotypes; (ii) smaller baseline volumes of brain structures, reflecting a more extensive neurodegeneration, predict disability accrual; (iii) the rate of regional volume loss is associated with the rate of disability accumulation.
Methods

Participants

In this retrospective study, we collected data from 7 European MS centres (MAGNIMS: www.magnims.eu) from 1,424 participants who have been studied between 1996 and 2016; we included participants who fulfilled the following criteria: (1) a diagnosis of MS according to 2010 McDonald Criteria or a clinically isolated syndrome (CIS); (2) healthy controls (HCs) without history of neurological or psychiatric disorders; (3) at least two-MRI scans acquired with a minimal interval of 6 months with identical protocol, including high-resolution T1-weighted MRI (allowing regional grey and white matter segmentation), and T2/Fluid Attenuated Inversion Recovery (FLAIR), sequences. Patients were scored on Expanded Disability Status Scale (EDSS). To increase the number of HCs scans, which were provided by 4 centres, we collected data from age-matched HCs from the Parkinson’s Progression Marker’s Initiative (http://www.ppmi-info.org/data).

MRI scans were taken under consent obtained from each subject independently in each centre. The final protocol for this study was reviewed and approved by the European MAGNIMS collaboration for analysis of pseudo-anonymised scans.

Image acquisition

We included scans from 13 different MRI protocols; all centres except one provided 3D-T1 weighted scans (Supplementary Table 1 and Supplementary Table 2 show the MRI protocols).

Image analysis

We performed image analysis as follows:
1) Bias field correction

We used N4 bias field correction to correct for field inhomogeneity in T1-weighted scans using ANTs v2.1021.

2) Lesion filling

Lesion masks were manually delineated on PD/T2 images by different raters at each centre semi-automatically, except for 3 centres that used the same automatic lesion segmentation with LST toolbox (version 2.0.15) 22. We calculated linear transformation matrices to register T2/FLAIR with the T1-weighted scan using FSL-FLIRT v5.023. Then we applied these matrices to lesion masks to transfer them into the accompanying T1 subject-space. We used the FSL lesion filling method which uses a white matter mask calculated with FSL-FAST24 to fill T1 hypo-intensities within normal-appearing whiter matter, so to reduce segmentation errors, as previously done25-27.

3) Symmetric within-subject registration

To avoid asymmetric registration and interpolation of longitudinal scans (e.g., toward the baseline scan), we constructed an unbiased subject-specific template that has “equal distance” from each time point using FreeSurfer version 5.328-30. We linearly transformed T1-weighted images to this symmetric space with the unbiased transformation matrix for each time point and used cubic B-spline interpolation to reduce interpolation artefacts. We manually checked the alignment of scans in the symmetric space.

4) Tissue segmentation

Next, in the symmetric space, we segmented T1 scans into the GM, white matter and cerebrospinal fluid with the Geodesic Information Flow (GIF) software (part of NifySeg, http://cmictig.cs.ucl.ac.uk/niftyweb/program.php?p=GIF)31, and parcellated each hemisphere into regions of interest according to the Neuromorphometric atlas32. GIF uses an atlas propagation and label fusion strategy to calculate the voxel probabilities of GM, white matter and CSF31; this method has been previously used in MS and other neurodegenerative
disorders. The template library had 95 MRI brain scans (HCs and patients with Alzheimer’s disease) with neuroanatomic labels (http://www.neuromorphometrics.com/). This atlas, which is similar to Mindboggle atlas, was developed to improve the consistency and clarity of Desikan-Killiany protocol.

To calculate brain masks and exclude segmentation errors outside of the brain we used STEPS (Similarity and Truth Estimation for Propagated Segmentations, http://cmictig.cs.ucl.ac.uk/niftyweb/program.php?p=BRAIN-STEPS) based on a template library of 682 hand-drawn brain masks. These maps were applied to each time point separately.

5) Regional volume calculation

We visually assessed the segmentations to assure the quality for statistical analysis. To calculate regional volumes, we summed the probability of the segmented tissue voxels (GM or white matter) in each parcellated region and multiplied the sum with the voxel volume. We averaged values between left and right hemispheres. Next, we summarised the regional volumes according to Neuromorphometrics protocol by summing the volume of GM regions in the temporal, parietal, occipital, frontal lobes, cerebellum and deep GM (DGM) [thalamus, putamen, globus pallidus, caudate, and amygdala]. We also obtained the volume of the brainstem and of the cerebral white matter.

Figure 1 shows the image analysis pipeline.

Statistical analysis

Brain volumes at baseline and rates of volume changes over time

To investigate baseline volumes (intercept) and rates (slopes) of volume change by subject group and region, we used linear mixed-effects models with the volume at a given time as the
response variable, and time and interactions with time as fixed-effect covariates. This model estimates adjusted rate while allowing for nested correlation structures, such as time of visit within subject within scanner, by incorporating, in this example, subject and scanner random intercepts, and a random slope on time. The interaction terms with time (e.g., subject group X time), allows the estimation of rate differences across the interacting variable, in this example subject groups or clinical phenotypes. Including another interaction with time, such as gender X time, adjusts the rate for gender. In addition to time, the fixed-effect covariates were: scanner magnetic field, subject group, gender, age at baseline, total intracranial volume (sum of the volumes of GM, WM and CSF) at baseline; and the interactions of each of these with time. Disease duration was too highly correlated with age at baseline to give reliable estimation, and was omitted from the final models. To estimate the percentage changes per unit (year) increase in time, we log-transformed the volume. We adjusted time to zero for those visits in which a patient converted from one phenotype to another (e.g., CIS to RRMS). We performed post-hoc analyses to identify specific GM regions within the cerebral lobes and among the DGM nuclei that showed significant differences between MS phenotypes, as well as the default-mode network regions.

To investigate whether there is an association between the rate of loss in specific regions and MS phenotypes, 3-way interactions were used, for example, clinical phenotype × region × time. We used R (version 3.2.2) and the NLME package.

For each model, we visually checked the heteroscedasticity (which is the unequal variance of a variable across the range of values of a second variable that predicts it) per group by plotting residuals against the fitted values.

We corrected for multiple comparisons accounting for the number of all the tests performed with the false-discovery rate method.

**Effect of MRI protocols on imaging measures**
To assess the effect of the MRI protocol on MRI measures (we took into account the protocols rather than the centres because some centres acquired more than one protocol with more than one scanner) we included it as a fixed-effect variable in a separate mixed-effect model, and calculated the average effect sizes for MRI protocols and MS phenotypes (i.e., disease effects) while fixing other variables.

Assessing associations between brain tissue volumes and disability accrual

For easier interpretation of clinical and imaging measures, we standardised volumes by subtracting the mean and dividing by the standard deviation (Z-score). We analysed CIS and relapse-onset patients together, because some patients had converted from CIS to RRMS, or from RRMS to SPMS. This allowed us to take advantage of a longer follow-up period. With similar mixed-effects models we investigated the following three questions: (1) Are the baseline volumes of the DGM, the temporal, frontal, parietal, occipital and cerebellar GM, brainstem, and white matter, and white matter lesion load associated with EDSS at baseline? (2) Are changes in all these regional volumes and white matter lesion load associated with EDSS changes over time? (3) Do baseline volumes of all these regions and white matter lesion at baseline predict time-to-EDSS progression (event=EDSS progression) during follow-up? The EDSS-progression event was defined as 1.5 increase in EDSS, if the baseline EDSS was 0; one-point increase if EDSS was less than or equal to 6; and 0.5 increase if EDSS was more than 6. We used a Cox-regression model to explore whether baseline volumes of these structures predicted time to event. We performed a *post-hoc* analysis using all GM regions to determine the most important predictors of time-to-EDSS-progression (as defined above) and confirm that the results of the DGM were not affected by the bias of merging a higher number of cortical regions into the main lobes. We performed FDR correction to adjust for multiple comparisons.

Additional analyses: software reliability and effects of disease modifying treatments
We carried out additional analyses to assess the reliability of brain volumes estimated with GIF software, FSL-FIRST, and SPM12, and effects of treatments on atrophy measures. We also performed area under the curve (AUC) analysis to examine the prognostic accuracy of adjusted DGM volumes at individual level (see Supplemental Material).
Results

The MRI scans of 1,417 subjects were analysed (scans of three subjects were excluded due to significant motion artefacts on visual inspection and four due to registration issues because of missing MRI header information); 1,214 patients (253 had CIS, 708 had RRMS, 128 had SPMS, and 125 had PPMS), and 203 were HCs. In total, we analysed 3,604 T1-weighted MRI. Average number of scans per subject was 2.54 (SD=1.04), with an average follow up of 2.41 years (SD=1.97) for patients, and 1.83 (SD=1.77) years for HCs (see Table 1 for follow-up information per group). The total numbers of participants with 3 or more visits for each group were: 90 HCs, 48 CIS, 334 RRMS, 39 SPMS, and 58 PPMS. A total of 96 patients with CIS (38%) converted to RRMS, and 28 patients with RRMS (4%) converted to SPMS during the follow-up.

There was a significant difference in gender ratio between groups ($p<0.001$, see Table 1 for gender ratios). Patients with progressive MS (SPMS and PPMS) had significantly greater disability than patients with RRMS and CIS (Mann-Whitney tests, $p<0.001$, see Table 1), and were older than RRMS ($p<0.001$, average difference=10.7 years), CIS ($p<0.01$, average difference=15.6 years) and HCs ($p<0.01$, average difference=10 years). Age was similar between patients with RRMS and HCs. Patients with CIS were younger than HCs ($p<0.01$, average difference=4.9 years). Patients with CIS had the lowest T2 lesion load, and patients with SPMS had the highest T2 lesion load. About half of patients with RRMS were on disease modifying treatments (see Table 1).

<... ... Table 1 ... ... >

**Brain atrophy at baseline in MS and rates of volume changes over time**

At baseline, all clinical phenotypes (CIS, RRMS, SPMS, and PPMS) had significantly smaller cortical GM and DGM volumes than HCs. SPMS showed the lowest cortical GM and DGM volumes, followed by PPMS, RRMS, CIS. All clinical phenotypes, but not CIS, had
significantly reduced whole brain and white matter volumes when compared to HCs (see Figure 2A).

The fastest regional decline in tissue volume over time was seen in the DGM in all clinical phenotypes (PPMS: -1.66% per year, SPMS: -1.45%, RRMS: -1.34%, CIS: -0.88%, p<0.01) and in HCs (-0.94%). The rate of atrophy in the DGM was greater in RRMS, SPMS and PPMS than CIS and HCs (all p values <0.01) (Figure 2B and Supplementary Tables 3 and 4), but did not differ between RRMS, SPMS and PPMS. The rate of volume loss in the DGM in all MS patients together was significantly higher than that in the cortical and cerebellar GM and brainstem (although the rate of volume loss over time in these areas was still significant) (all p values < 0.05).

The volume loss of the whole cortical GM was faster in SPMS (-1.11% per year), PPMS (-0.79%), RRMS (-0.67%), than HCs (-0.34%)(all p values <0.05). Among the cortical regions, the temporal lobe GM showed a faster volume loss in SPMS (-1.21%) than RRMS (-0.77%) and CIS (-0.75%) (all p values <0.05) (Figure 2B and Supplementary Tables 3 and 4). Similarly, the parietal GM showed a faster volume loss in SPMS (-1.24%) than CIS (-0.63%) (p<0.05) (Figure 2B and Supplementary Tables 3 and 4). No differences in rates of volume loss were seen in the frontal and occipital GM between clinical phenotypes. Overall, all the cortical GM regions, with the exception of the occipital cortex, showed a faster rate of atrophy in MS than HCs (Figure 2B and Supplementary Table 4).

The white matter did not show a significant rate of volume loss in HCs or any of the clinical phenotypes.

There was no heteroscedasticity in the plots of residuals against fitted values.
In the *post-hoc* analyses when looking at regions and clinical phenotypes we found that among the DGM nuclei, the putamen showed the fastest volume loss in PPMS (-2.6%). Within the temporal lobe GM, the fastest volume loss was seen in the temporal pole (-1.47%) and posterior insula in SPMS (-1.19%). When looking at the parietal lobe GM, the precuneus showed the fastest atrophy rates in SPMS (-1.28%) ([Figure 2C](#)). Whilst the fastest rate of atrophy was seen in DGM in SPMS, the temporal lobe GM showed the highest difference between SPMS and HCs (see [Figure 2C](#)).

There was no significant effect of gender on rates of atrophy. There was no significant association between GM volumes and T2 (or FLAIR) lesion load.

*Regions showing the highest rate of loss*

When we compared the rate of volume loss across different regions in all patients (CIS, RRMS, SPMS, and PPMS) together, the fastest decline (or lowest slope) was seen in the DGM ([Supplementary Tables 3 and 4](#)). The rate of loss in the cortical GM regions was similar between lobes and to that of the cerebellum. The slowest rate of loss was seen in the brainstem.

*Spatiotemporal pattern of GM volume loss in clinical phenotypes*

Although SPMS showed the lowest baseline volumes of cortical GM and DGM, and the rate of the DGM volume loss was faster in SPMS, PPMS and RRMS than CIS and HCs, there was no significant association between the rate of loss in specific regions and clinical phenotypes, which suggests that all clinical phenotypes share a similar spatiotemporal pattern of GM loss.
**Effect of MRI protocols on imaging measures**

The average effects of MS phenotypes on brain volumes at baseline were higher than the protocol effect on the brain volumes (protocol effects: whole brain = 4.3%, cortical GM = 5.1%, DGM = 8.5%, disease effects: whole brain = 4.8%, cortical GM = 5.2%, DGM = 13.7%). The average effects of MS phenotypes were higher than the effects of protocol on the rates of atrophy of the cortical GM and DGM (protocol effects: cortical GM = 0.14%, DGM = 0.21%, disease effects: cortical GM = 0.57%, DGM = 0.53%), but not those of the whole brain (protocol effect = 0.51%, and disease effect = 0.38%).

**Association between EDSS and GM loss**

In all clinical phenotypes combined, lower DGM and cortical GM volumes at baseline were associated with higher disability, as measured by the EDSS ($\beta$: DGM $\beta$ = -0.71, $p<0.0001$; cortical GM ($\beta$ = -0.22, $p<0.0001$). Under the assumption of a linear relationship between EDSS and GM volume, this suggests that for every Z-score decrease in the DGM and cortical volume at baseline, the baseline EDSS increased on average by 0.7 and 0.22, respectively.

There was a significant progression of EDSS in both relapse-onset and PPMS patients, which on average increased by 0.07 and 0.2 per year, respectively. When we examined associations between the rate of EDSS changes and rate of changes in the volumes of cortical GM regions, cerebellar GM and DGM over time, only the rate of loss in the DGM was associated with disability accumulation ($\beta$ = -0.04, 95% CI: -0.02, -0.06, $p=0.006$). Under the assumption of a linear relationship between EDSS and rate of GM volume loss over time, this suggests that every standard deviation (Z-score) loss in the rate of DGM volume corresponded to an annual EDSS gain of 0.04.

The percentage of patients who had EDSS progression during follow-up (or who experienced the “event”) was 26%. When we looked at baseline predictors of disability accumulation,
without any longitudinal imaging measure in the model, only the DGM predicted future EDSS progression. The hazard ratio [95% CI, p-value] for time-to-EDSS progression was 0.73 [95% CI 0.65, 0.82, \( p < 0.0001 \)], which suggests that for every standard deviation (Z-score) decrease in the DGM volume at baseline the risk of presenting a shorter time to EDSS worsening during the follow-up increased by 27% [95% CI: 18-35%]. The hazard ratio remained similar when we analysed relapse-onset and PPMS patients separately (0.72 and 0.73 respectively). Figure 3 illustrates the survival-curve for these analyses.

<... ... Figure 3 ... ... >

In the post-hoc analyses, baseline thalamic volume had the highest predictive value of EDSS-progression during follow-up in both PPMS and the relapse-onset groups, by increasing the risk to a shorter time to EDSS worsening of 37% in relapse-onset MS and 40% in PPMS (Figure 4B and C). In this analysis, the predictive value of the thalamus was followed by that of the hippocampus and angular gyrus in relapse-onset MS (Figure 4B), and by that of the putamen, posterior insula and temporal pole in PPMS (Figure 4C).

<... ... Figure 4 ... ... >

There were no significant differences in the rates of loss in patients who were receiving disease-modifying drugs and those who were not (see Supplementary Text). The analyses with GIF software, FSL-FIRST, and SPM12 confirmed the reliability of brain volumes estimates (see details in Supplementary Text). AUC analysis showed that DGM volumes were similar to a random classifier in prognosticating individual patients (see details in Supplementary Text).
**Discussion**

In this large multicentre study, we have shown that volume loss in DGM over time was faster than that seen in other brain regions across all clinical phenotypes, and DGM volume loss was the only GM region associated with disability accumulation. Additionally, we found that the smaller DGM volume at baseline was associated with increased risk of shorter time to EDSS progression, in agreement with previous studies that showed smaller DGM volume associated with higher disability\textsuperscript{14,15}. Interestingly, we found that atrophy rates of the GM of cortical lobes were the fastest in SPMS, and were faster in the temporal lobe in SPMS in comparison with RRMS and CIS and in the parietal lobe in SPMS in comparison with CIS. However, no significant association between cortical regions and disability progression was detected. Overall, our findings suggest that the development of DGM atrophy may drive disability accumulation irrespective of clinical phenotypes, thereby becoming a useful outcome measure in neuroprotective clinical trials. Although the spatiotemporal pattern of atrophy remains similar across MS phenotypes, some cortical regions show accelerated atrophy in SPMS than RRMS and/or CIS. We now discuss these results in turn and in detail.

The pathological events that underpin DGM atrophy are not known, but this is generally interpreted as the result of neurodegeneration. Previous studies have shown that DGM atrophy is more severe in patients with progressive MS, longer disease duration and worse cognitive performance \textsuperscript{14,15,43}. Our *post-hoc* analyses showed that the thalamus, which is the DGM’s largest component, was a better predictor of future disability than other regions, and the rate of atrophy in the putamen was the highest across DGM nuclei. Previous studies, including those using advanced MRI, have found that thalamic damage at study entry was associated with higher disability\textsuperscript{13–15}. DGM structures are extensively connected with cortical GM regions, and therefore DGM atrophy could be due to retrograde and anterograde neurodegeneration via tracts that connect GM areas. For example, the extent of cellular
density loss in the thalamus, is associated with neurodegeneration in the remote (but connected) cortical regions, over and beyond the extent of atrophy explained by demyelination in connecting tracts\textsuperscript{44}. There is also evidence of other neurodegenerative mechanisms in the DGM nuclei. For example, their higher load of iron than other regions can accumulate oxidised lipids which are associated with neurodegeneration\textsuperscript{45}. In our healthy controls, the rate of DGM atrophy was faster than that in other regions, suggesting that it may be a hot spot for both age- and disease-related atrophy in the human brain, although a methodological issue, related to its more uniform structure than other brain regions, cannot be excluded. In AUC analysis we found that at the individual level, DGM volume lacks prognostic value, which is due to the high variability typical of volumetric MRI studies\textsuperscript{46}. Nevertheless, the DGM volume holds strong promise as a marker of disease progression (at the group level) with the potential to respond to neuroprotective treatments that target neurodegeneration in MS.

Interestingly, the temporal lobe showed a significant acceleration in SPMS when compared to both RRMS and CIS. Similarly, the parietal lobe GM showed a significant acceleration of atrophy in SPMS in comparison with CIS. Our post-hoc analysis showed that the temporal pole and insula were the most affected structures in the temporal GM. Pathological studies have demonstrated an increase in the rate of neurodegeneration, especially in the temporal regions, during progressive stages of MS in comparison with RRMS and CIS\textsuperscript{47,48}. Overall, a global pathological process in MS\textsuperscript{49}, may become more pronounced in certain regions, such as the temporal GM, because of other mechanisms, such as static exposure to CSF (the insula in the temporal lobe) or hypoxia in watershed areas (some DGM nuclei such as the pallidum).

For example, meningeal inflammation and cortical demyelination, which may play a role in cortical atrophy, preferentially affect deep sulci, such as the insula, where there is more exposure to static inflammatory cytokines\textsuperscript{2}. Our findings also suggest that regions with more connections may be vulnerable to atrophy. For example, among the parietal cortical regions,
the precuneus, a core part of an important functional brain network (default mode network), showed the fastest atrophy rates in SPMS\textsuperscript{39}. Thus, acceleration of atrophy during SPMS may be explained by cortical network collapse with advancing of degeneration from initial injury sites (focal lesions in the white matter or initial DGM degeneration) to interconnected neocortical systems\textsuperscript{50}. We found that MS phenotypes shared a common spatiotemporal pattern of volume loss (no significant 3-way interaction of time $\times$ region $\times$ phenotype). This shows, in line with previous studies, that the difference in pathology of progressive MS is only quantitative rather than qualitative in comparison with RRMS\textsuperscript{2,51}.

Cortical GM atrophy was seen at study entry across clinical phenotypes, even in CIS, when compared with HCs, and was the greatest in progressive MS, in agreement with earlier studies\textsuperscript{17,52}. Our findings of faster whole brain atrophy in SPMS, PPMS, RRMS than CIS, who in turn, showed higher cortical atrophy than HCs, are similar to previous studies on longitudinal whole brain atrophy\textsuperscript{5,53,54}, regional atrophy\textsuperscript{17,55–57}, and pathology of MS phenotypes\textsuperscript{2,47}. Our study confirms our previous findings that relationships between whole brain atrophy and clinical changes are weak or absent\textsuperscript{5}, and shows DGM atrophy as a stronger marker of clinical disability. Although the GM volumes of cortical lobes could not predict future EDSS progression, the more detailed post-hoc analyses showed that regional volumes, such those of the hippocampus and the angular gyrus, were associated with future EDSS progression. These regions are highly connected to other regions, and especially the angular gyrus (like the precuneus) acts as a hub in the default mode network, which could make it vulnerable to atrophy, as explained above\textsuperscript{39}.

This study was not designed to assess the effect of treatment on atrophy rates, but does study atrophy while adjusting for possible confounding effects. The rates of atrophy in all clinical phenotypes were similar in people who were receiving disease-modifying treatments to those
who were not. Even though we could not ascertain the duration of treatments due to retrospective nature of this study, the majority (90%) of patients on disease modifying treatments, were receiving first-line injectable drugs (interferon or glatiramer acetate) before study entry. The effects of these drugs on brain atrophy are modest at best \(^{58,59}\). Therefore, drug effects are unlikely to be confounders of our analysis.

One strength of our study is that we included a large number of patients, who underwent the same protocol on the same MRI scanner over time at single sites. However, different MRI protocols could have an effect on atrophy measures and is a limitation of our study\(^ {60,61}\). We therefore used a hierarchical statistical design based on scanner. Our study was powerful enough because the effects of clinical phenotype on the regional rates of atrophy were higher than the effects of between-centre variation.

We chose GIF software to segment and parcellate the brain\(^ {31}\) because it allowed inclusion of 2D MRI data (which we had for one centre), and did not require any manual editing, unlike Freesurfer, which would have been unfeasible for such large number of scans. Our reliability analysis showed excellent agreement between GIF-derived DGM volume and that obtained using FSL-FIRST, and between GIF-derived cortical volumes and those obtained using SPM12, respectively. Therefore, we chose to present the results obtained with GIF because it allowed us to rely on only one method to segment DGM and cortical GM, and estimate TIV. We used TIV to adjust for variations in head size, rather than the skull-size, so that a more reliable estimate of head size is obtained, irrespectively of the field-of-view, the choice of the inferior cut-off of the brain for the analysis, and demographic factors (e.g., age, or weight)\(^ {62}\).

With regard to the statistical methods, we used mixed-effects models to calculate atrophy rates\(^ {41}\), which naturally accommodated multiple (3 or more) time-points with varying intervals between follow-ups, and patients who convert from one phenotype to another (e.g., CIS to RRMS). These two issues are cumbersome to address with methods that rely on
pairwise comparisons (e.g., SIENA, BSI) and suffer from higher variance in brain atrophy estimates as the interval between two scans increases\textsuperscript{63,64}. Mixed-effects modelling, instead, estimates a variance component to eliminate implausible inconsistencies\textsuperscript{65,66}. Based on our experience and the results of this study, we recommend the acquisition of high-resolution 3D-T1 images (isotropic 1mm\textsuperscript{3}). Several methods can calculate DGM volumes, such as FSL-FIRST, and GIF. We recommend the use of the GIF software when it is desirable to use the same method to segment both the cortex and DGM.

There were also limitations in this study. The majority of centres did not provide MRI scans of HCs, however, we included a large number of HCs including those from an external initiative (PPMI). Our findings of volume changes in HCs were consistent with the literature. Meta-analyses have shown, in individuals less than 70 years of age, rate of whole brain loss ranges from 0 to -0.5 (our study = -0.04), GM loss ranges from 0 to -0.5% per year (cortical GM in our study = -0.34\%\textsuperscript{67}, and the subcortical structures may show loss of up to -1.12\% (DGM in our study = -0.94)\textsuperscript{68}. Cognitive functions were not tested, and it is unknown whether cortical patterns of GM atrophy over time were associated with cognitive impairment. Clinical trials in MS (and in progressive MS in particular) include confirmed disability progression, based on the EDSS, as primary outcome measure. Although for EDSS the model-estimated coefficients and their p-values and confidence intervals are valid for comparison between brain regions, the absolute value of these coefficients must be interpreted with caution, because the EDSS does not have a uniform linear interpretation. Since this was a retrospective study, the duration of treatments before entry to the study could not be ascertained for all participants. Disease modifying drugs may have lasting effects, for example they may slow the accrual of disability after a decade\textsuperscript{59,69}. Moreover, MRI sequences sensitive to cortical lesions were not available, and the effects of cortical lesions on atrophy measures remain unknown.
In conclusion, the DGM atrophy showed the most rapid development over time– extending previous cross-sectional studies that showed a relationship between DGM atrophy and disability– was most closely associated with disability accumulation and predicted the time to EDSS worsening. In phase II trials of neuroprotective medications in MS, DGM atrophy measures may therefore have greater potential to show treatment effects than other regional GM or whole brain measures. There was a disconnect between DGM atrophy and cortical atrophy rates. The temporal and parietal cortices showed a faster rate of atrophy in SPMS than RRMS and/or CIS, whilst DGM showed a faster rate of atrophy in SPMS than CIS only, suggesting that neurodegeneration in GM regions may proceed at a different rate which should be taken into account in the design of clinical trials.

Table legend: Abbreviations: SD, standard deviation; CIS, clinically isolated syndrome; RRMS, relapsing-remitting multiple sclerosis; SPMS, secondary-progressive multiple sclerosis; PPMS, primary-progressive multiple sclerosis; ml, millilitre; EDSS, expanded-disability status scale; DMTs: disease modifying treatment.
Figures Legends:

**Figure 1. Imaging analysis pipeline.** An unbiased symmetric image registration approach was used to calculate atrophy.

**Figure 2. Baseline volumes, and annual percentage loss of brain regions in clinical phenotypes and healthy controls.** Adjusted baseline values for HCs, CIS, RRMS, SPMS, and PPMS are shown in (A), where the adjusted mean is shown as a point, and error bars show the 95% confidence-interval. Adjusted $P$-values of pairwise comparisons between groups are shown in Supplementary Table 4. Longitudinal analyses are shown in (B) and (C). Bar charts of the adjusted annual percentage of loss are shown in (B) for the predefined regions. Height of each bar chart is the average estimate of the percentage annual loss from the mixed-effects model for each group. The error bars represent 95% confidence interval of these estimates. Adjusted $P$-values for pairwise comparison between regions across clinical phenotypes and HCs are shown in Supplementary Table 4. White matter volumes are not shown in (B, and C) because they did not show a significant change over time in any clinical phenotype. Post-hoc analyses of annual percentage loss are shown in (C) where DGM nuclei, temporal, limbic and default mode network regions were selected. Similar to (B) the adjusted average annual percentage volume loss for these regions is the height of each bar-chart and error bars represent 95% confidence intervals.

Baseline values (A) and rates (B, and C) were adjusted in a single mixed-effects hierarchical model including age, gender, total intracranial volume at baseline, scanner magnetic field, and their interactions with time as the fixed-effects. Centre, subject and visits were nested (hierarchical) random-effects.
Abbreviations: HC, healthy controls; CIS, clinically isolated syndrome; RRMS, relapsing-remitting multiple sclerosis; SPMS, secondary-progressive multiple sclerosis; PPMS, primary-progressive multiple sclerosis.

**Figure 3. DGM volume predicts future progression of EDSS.** Survival curves for time to event (sustained EDSS progression, see methods for definition) in CIS, relapse-onset and PPMS. We have analysed CIS and relapse-onset patient together, because a proportion of patients convert from CIS to RRMS, or from RRMS to SPMS during the course of study. Hazard-ratios for models with continuous outcome variables (regional volumes) are reported.

**Figure 4. Risk of EDSS-progression during follow-up for each Z-score volume loss of the brain regions at baseline (post-hoc analysis).** Results of the post-hoc Cox-Proportional Hazards univariate models are shown for the time-to-event analyses (event = sustained EDSS-worsening, see methods for the definition) in the regions of Neuromorphometrics’ atlas, which are shown in (A). The predictors were the baseline volumes of the regions shown in the x-axes of (B) for CIS, RRMS, and SPMS and (C) for PPMS. CIS, RRMS, and SPMS were analysed together, because several patients convert from one phenotype to another. Brain maps are shown in the left column, and bar-charts of the same analyses are shown in the right column of (B) and (C). Only regions whose P-value of the survival analysis survived FDR-correction (adjusted $P<0.05$) are shown in (B) and (C). The y-axes show the risk of progression for each Z-score loss in the volume of the corresponding brain region on x-axes. For example, for every Z-score loss of the thalamus volume at baseline, the risk of EDSS worsening during follow-up increased by 37% for the CIS, RRMS, SPMS group, and 40% for PPMS. Colour maps code the importance of baseline volumes of the regions to predict EDSS-worsening (or EDSS-progression) during follow-up. The absolute values of
coefficients for ventricular volumes are shown in (B), because they have an effect in the opposite direction of other structures. Error-bars indicate the 95% confidence intervals.
