## ***Abstract***

Children pose a problem. The extended period of childhood dependency and short inter-birth intervals mean that human mothers have to care for several dependent children simultaneously. It has long been argued that this is too much of an energetic burden for mothers to manage alone, and that they must enlist help from other relatives to share the costs of raising children. Which kin help is the subject of much debate. Here, we review the evidence for whether the presence of kin affects child survival rates, in order to infer whether mothers do receive help in raising offspring and who provides this help. These 45 studies come from a variety of (mostly) natural fertility populations, both historical and contemporary, across a wide geographical range. We find that in almost all studies, at least one relative (apart from the mother) does improve the survival rates of children, but that relatives differ in whether they are consistently beneficial to children or not. Maternal grandmothers tend to improve child survival rates, as do potential sibling helpers at the nest (though the latter observation is based on rather few studies). Paternal grandmothers show somewhat more variation in their effects on child survival. Fathers have surprisingly little effect on child survival, with only a third of studies showing any beneficial effects. Overall, this review suggests that while help from kin may be a universal feature of human childrearing, who helps is dependent on ecological conditions.

## 21    **1.0    *Introduction***

22            Human life history poses a problem for women: that of raising several dependent  
23 children simultaneously. The human birth interval, of about three years in natural fertility  
24 populations, is out of line with that of other great apes of similar body size. The orang-utan,  
25 for example, has an interbirth interval of about eight years, and the chimpanzee four-five  
26 years (see Galdikas & Wood, 1990 for a review). If human females are capable of such rapid  
27 reproduction, most anthropologists agree that this is due to the support they receive from  
28 other family members. The ‘traditional view’ has been that this help comes from the father –  
29 hence the human pair-bond is based on mutual interdependence of husband and wife to raise  
30 their children (e.g. Lovejoy, 1981). In hunter-gatherer societies, the division of labour is  
31 nearly always such that men bring back meat to the band, whereas women gather. However,  
32 the importance of the male contribution to the subsistence of the women and children has  
33 been questioned (Hawkes, 1990). The observation that the number of calories brought back  
34 from gathered foods often exceeds that from hunting, combined with the fact that meat is  
35 often shared widely throughout the band rather than strictly within the nuclear family  
36 (Hawkes et al., 2001; Kaplan & Hill, 1985), has lead to the suggestion that women are not as  
37 dependent on men to raise their family as once thought (Hawkes et al., 1997).

38

39            If human life history poses a problem for women, then it may also provide the  
40 solution. Unusually, human females spend a relatively high proportion of their lives in a non-  
41 reproductive state. Both pre- and post-reproductive individuals may be available to help  
42 mothers in raising offspring, as they can do so at relatively little cost to their own  
43 reproduction. Grandmothers, in particular, are often proposed as an alternative to male care.  
44 If grandmothers are helping to support their daughters’ children, then two unusual features of

human female life history – menopause and high birthrates - can potentially be explained at once. Both may arise because menopause is an adaptation to enable grandmaternal support, which in turn enables a high human birth rate (Hawkes et al., 1998). Mothers may also use the labour of their older children, particularly daughters, to spread the costs of raising offspring. The extended juvenile period of human young is another unusual characteristic of our species, and the economic contributions of older children may also help to underwrite the costs of large family size (Kramer, 2005; Lee & Kramer, 2002#2374).

## **1.1 Who supports the family in hunter-gatherer societies?**

How might empirical studies help us to distinguish between the two views of the human family: that the pairbond with the father is key, or that other kin, especially grandmothers, are more important as allocarers? Empirical studies on hunter-gatherer communities are data-limited, due to both the very small number of such societies that survive, and the very small number of individuals living in something approaching a hunter-gatherer lifestyle within those societies. This may have contributed to the fact that a consensus view on the relative importance of fathers as compared to grandmothers has not emerged.

The main line of evidence in this debate came from nutritional studies. Hawkes et al. (1997) point out that in the Hadza of Tanzania, children with older female relatives in their band are better nourished, and their data suggest that the hunting season is not actually a particularly good time of year for children (see also Hadley, 2004). Studies on foraging strategies in the Ache of Paraguay and in the Hadza highlight the fact that total calories and energy return rates from gathering often equal or even exceed that from hunting (Blurton Jones et al., 2000; Hill et al., 1987; Marlowe, 2003). Isotope studies on pre-historical

Californians suggest that male and female diets were so different that they appeared to be almost on different trophic levels (Walker & Deniro, 1986); the males appeared to have been living almost entirely off marine resources whereas the females must have been eating food almost exclusively terrestrial in origin. This suggests that food sharing between the sexes was minimal. But Hill, Kaplan and others (see e.g. Gurven & Hill, 1997; Gurven & Kaplan, 2006; Hill, 1993; Kaplan & Lancaster, 2003) have argued that the nature of the food brought back by males is superior and very important, leading them to conclude that the contribution of males to family nutrition is very significant (though note that an important contribution by males to the diet does not necessarily imply that fathers are directly provisioning their families). As an extreme example, Arctic hunters like the Inuit are almost entirely dependent on hunted food brought in by men. In the coldest areas, babies and young children could barely survive outside for much of the year, and thus females are dependent on their spouses for almost everything. And Marlow (2003) shows that male provisioning occurs at very important times in the Hadza, such as when a woman's foraging is handicapped because she recently gave birth.

These findings suggest that the ecology of the system influences the relative importance of fathers, grandmothers, and potentially other kin such as siblings or older offspring, in the rearing of human children. This should come as no surprise to evolutionary ecologists. The variability in hunter-gatherer ecology further highlights the fact that data from just one type of population cannot answer the question of whether humans are co-operative breeders. We will argue here that it is not necessary or sufficient to restrict our studies to extant hunting and gathering communities, none of which are necessarily cases of special importance in human history. Furthermore, very few hunter-gatherer studies can generate large enough sample sizes to estimate important determinants of rare events like mortality, or

low variance measures like fertility. There are a small number of natural fertility and natural mortality populations for which large sets of demographic data are available, some of which are historical populations. These are now being analyzed to enhance our understanding of which kin have an influence on the fitness of their descendants. Most of these populations are farmers, but farmers with high workloads, high disease burdens and high reproductive rates. Whilst most of these populations are/were growing rather than stable, the same can be said of contemporary hunter-gatherers populations too. We need to use as much data as is available to us to untangle the full story of the evolutionary ecology of human family life.

## ***2.0 Kin effects on child mortality in a range of natural fertility/natural mortality populations***

There are many studies on the contributions of various relatives to childcare, nutrition and other aspects of development (Hewlett et al., 2000; Hurtado & Hill, 1992; Ivey, 2000) that contribute greatly to our understanding of social networks and child-rearing, but it is not always easy to determine from these studies the extent to which such help enhances the fitness of the beneficiary. In this review we shall concentrate solely on studies that have examined the effects of kin on one specific component of fitness: child mortality. For women, at least, child survival may be the most important determinant of reproductive success (Jones, 2005; Strassmann & Gillespie, 2002), since women (compared to men) have relatively low variance in fertility. Improving the survival chances of a woman's children may be the most important thing relatives can do to increase her reproductive success.

This review includes 45 populations in which the impact of at least one category of kin on child mortality has been investigated. Most populations had little or no access to

119 modern medical care, including contraception. A few studies do include data from  
120 populations which are moving through the demographic transition, so cannot strictly be  
121 described as natural fertility, natural mortality populations, but are nevertheless from  
122 societies in which child mortality is sufficiently high to demonstrate variation according to  
123 the presence or absence of kin. Such studies correlating the presence (often approximated by  
124 the survival status) of relatives with the survival of children do, of course, need to be  
125 interpreted with caution. Correlational studies are helpful, but suffer from the usual problem  
126 of attributing causation. Given that kin can share not only genes but frequently much of the  
127 same environment, there is a high possibility that confounding variables, not included in the  
128 analysis, are of great significance. Appropriate statistical analysis needs to be employed to  
129 minimise the chance that confounding factors will obscure genuine kin effects or result in  
130 false positives (Allison, 1984; Singer & Willett, 2003). Ideally, longitudinal datasets should  
131 be analysed using event history analysis (which allows a sensitive analysis of the effects of  
132 time-dependent variables, such as the presence of relatives, on the probability of dying over  
133 time), and including control variables for potentially confounding factors. As not all studies  
134 which have investigated this topic have used such adequately controlled statistical analysis,  
135 we have divided the sample into two groups. The statistically valid sample (n=31) includes  
136 only those studies in which at least some attempt was made to statistically control for  
137 confounding factors. Not all of these studies are longitudinal, nor do they all use event history  
138 analysis, but all have recognised the importance of confounding factors and tried to control  
139 for them in some way. The supplementary studies (n=13) present data on the impact of  
140 relatives but either do not attempt statistical analysis to demonstrate associations, or have not  
141 adequately controlled for possible confounding variables (i.e. only univariate analysis was  
142 used). The statistically valid and supplementary studies do not sum to 45 because one study  
143 (Derosas, 2002) presented an appropriately controlled event history analysis investigating the

effects of grandparents, but only descriptive data (and no statistical analysis) on the effects of parents.

We have presented the data in three sets of tables. Tables 1a and 1b give details of the effect of the presence of the mother on child survival (Table 1a shows the statistically valid sample, Table 1b supplementary data). Tables 2a and 2b demonstrate the effects of other kin on child survival (Table 2a the statistically valid sample, Table 2b supplementary data). In these tables, ‘+’ indicates that the presence of a particular relative improves child survival, ‘-’ that the relative lowers survival and ‘none’ the relative has no effect. Brackets indicate that the relationship was of borderline significance ( $0.05 > p > 0.1$ ), only applied to certain children (e.g. boys or girls) or was otherwise qualified. In several cases, the kin effects only applied to children of certain ages. These age-specific effects are mentioned in the ‘Other effects and notes’ columns. Blank cells indicate that category of relative was not included in the study. Table 3 provides a numerical summary of the previous four tables, and shows the number of studies which have found positive, negative or no effects of each relative on child survival.

### ***3.0 Who keeps children alive?***

#### **3.1 The importance of mothers**

It comes as no surprise that in all 28 populations in which the association between mother’s death and child death has been investigated, the death of the mother is clearly associated with higher child mortality (Tables 1a and 1b). That this effect exists is expected. What we wanted to determine from this analysis was firstly, how long this association lasted (i.e. is it seen throughout the whole period of childhood, or do mothers only matter to young children?), and secondly, can even young children survive the loss of their mothers? If this

association is confined to young children, and if children are able to survive the loss of their mother, this would indicate that other relatives are stepping in to help children out, if their mothers die.

Tables 1a and 1b indicate that the mother effect is strongly dependent on the age of the child. The consequences of losing a mother in very early life are catastrophic, as evidenced by the tiny proportion of children who survive if their mothers die giving birth to them: only 1.6% of Swedish children survived such a maternal death in the 19<sup>th</sup> century, and 5% of Bangladeshi children in the late 1960s (although by the 1980s, 26% of children survived maternal deaths in the same Bangladeshi population). But a child's survival chances appear to improve rapidly with age. Much higher proportions of children manage to survive the death of their mothers if it occurs during their first year of life in some populations: 35% in 19<sup>th</sup> century Caribbean and 40% in 1920s US (though these studies only investigated survival to age 1 year); 50% in Burkina Faso, 40% in historical Sweden and 48% in historical Germany (all looked at survival of the child to at least age 6 years). Studies which have statistically investigated the timing of the mother effect confirm that the effect of mother's death on child survival weakens or even disappears entirely after children are weaned. Almost all of the 13 studies which have tested whether the mother effect varies with the age of the child found evidence that the effect declines substantially as the child ages (11 found a decline with age; of the remaining two, one only investigated child mortality up to the age of five years, the other tested the timing of the effect for boys only). Five studies found that the mother effect disappeared entirely after the child reached two years of age.

Clearly, two year old children are not self-sufficient, so the good survival prospects of children who lose their mothers in later childhood must be due to other individuals taking

over childcare and provisioning. Tables 2a and 2b suggest who those individuals might be. These tables demonstrate clear evidence that the presence of kin is important in improving child survival. In every single study which has examined the impact of *multiple* family members on child survival (apart from the mother), at least one relative has a significant impact on child survival. This widespread importance of kin apart from the mother supports the hypothesis that women are cooperative breeders, sharing child-rearing with other family members. But which relatives help is less consistent than the fact of help itself.

### **3.2 How much do fathers matter?**

Every study that has compared the effects of the loss of mother and father on child survival found that the loss of the father has substantially less impact than the mother's death. Indeed, Tables 2a and 2b demonstrate that fathers frequently make no difference to child survival. Table 3 shows that in eight of the 15 populations studied using appropriate statistical techniques (53%) there is no association between the death of the father and the death of the child. If supplementary studies are included this proportion rises to 68% (15 of 22 studies). Even where associations between the loss of the father and increased child mortality are found, it is not clear that this is a direct result of the loss of paternal care. In at least one case where an association was found, the relationship was more likely to have been caused by mortality crises that killed family members simultaneously (such as infectious disease) rather than any causal effect of the loss of the father: Beekink et al. (2002) found that child mortality was only increased for one month after the death of the father (whereas the effect of the mother's death lasted considerably longer). In another case, that of rural Ethiopia, father absence increased the mortality of male infants only (Gibson, in preparation). This was interpreted as a Trivers-Willard effect, with father absence acting as a proxy for

household resources (father absence actually increased the survival of female infants in this population).

We interpret this variation in the impact of fathers as an indication that paternal investment in young children is facultative, and dependent on ecological conditions. Even where fathers are important for child survival, it is not clear that the benefits they bring to children are the traditionally assumed benefits of provisioning and economic support. Hurtado & Hill (1992) compared the effects of fathers on child survival in two South America hunter-gatherer groups. The loss of the father had a significant impact on Ache children, where marriages are unstable, meat widely shared among the group and fathers little involved in childcare, but no effect on Hiwi children, who are raised in nuclear families, with considerable input from the father in terms of both provisioning with meat and direct childcare. The importance of Ache fathers may instead lie in protecting their children from other males, rather than direct provisioning (infanticide of orphans was not uncommon in this group). Indirect evidence that the importance of fathers lies at least partly in protecting children from other males comes from studies of the impact of the mother's divorce and remarriage. Divorce and remarriage have been shown to increase a child's risk of dying (Alam et al., 2001; Bhuiya & Chowdhury, 1997; Sear et al., 2002). It is often not clear how much of this is due to father absence, to step-father presence or to mother absence (divorcing women may be unwilling or unable to take children with them), or indeed to the stress and violence of the divorce itself. But step-children have been found to be at greater risk of homicide than children living with natural parents (Daly & Wilson, 1988), and have higher stress levels than children living with both biological parents (Flinn & England, 1995).

241           Though these studies suggest that the importance of fathers in provisioning their  
242 young children has previously been overestimated, it does not mean that men do not invest in  
243 their offspring. Many of these analyses focus on relatively young children: 10 of the 22 father  
244 studies looked only at children under the age of five years. Such analyses may well  
245 underestimate the importance of fathers. The mortality risks of young children are likely to be  
246 highly dependent on the quality of care received (including lactation). Fathers can take no  
247 part in lactation, and in most populations take relatively little part in direct childcare (though  
248 there are exceptions: Hewlett, 1992; Huber & Breedlove, 2007), so may have little  
249 opportunity to affect the survival chances of young children, with the exception of protecting  
250 them from other males. Fathers may play more important roles in the lives of older children,  
251 teaching them subsistence skills and perhaps enhancing their marriage and fertility prospects.  
252 There is some evidence that women in traditional societies who lack fathers have later first  
253 births than those with fathers, suggesting fathers may be instrumental in arranging marriages  
254 for women (Allal et al., 2004; Waynforth, 2002). And Marlowe (2001) has found that male  
255 contribution to diet is positively correlated with female reproductive success in a cross-  
256 cultural study of hunter-gatherers, although male contribution was not associated with child  
257 survival.

258  
259           Secondly, the lack of a father effect may be because what fathers do for children can  
260 be more easily substituted than the services mothers provide to children. The care given to  
261 young children by reproductive aged women is usually directed exclusively towards the  
262 women's own children (i.e. lactation). There are rare cases of a lactating woman adopting and  
263 feeding an infant after the mother's death, but lactation is energetically costly and also  
264 inhibits conception, so that reproductive aged women can usually gain more from investing in  
265 their own offspring than looking after less closely related children. In contrast, the productive

work or protection that men provide for children can more easily be directed towards children other than their own. Though evidence does suggest that men are disinclined to invest in the progeny of other men (hence the role fathers play in some societies as protectors against other men), there are strategies that can be used to spread the ‘fathering’ role amongst other men. Hrdy (2000), in a review of the ethnographic literature on mating behaviour, suggests that women are more polyandrous than has been traditionally supposed. This polyandry functions in part to improve child survival by confusing or spreading paternity in order to protect children from potentially infanticidal males and/or encourage several males to invest in mothers and children. For example, in some South American hunter-gatherer communities, paternity is considered to be ‘partible’, i.e. any man who has sex with the mother around the time of conception and pregnancy is regarded as a father of the child. In both the Ache and among Bari hunter-gatherers of Venezuela, children with multiple fathers do better than those with only one (Beckerman et al., 2002; Hill & Hurtado, 1996) – though Ache children with many fathers did less well than those with one primary and one secondary father. An alternative strategy for spreading the fathering role may be patriliney, where patrilineally related men and their wives may live and work in close proximity. In such societies, patrilineally related males may take over the father’s responsibilities if a child’s father dies, especially where the levirate is practiced (women marrying their husband’s brother after widowhood). In the Gambian population we have studied, patrilineal live in extended family compounds, and the levirate is common (around 40% of widows married their dead husbands’ brothers). Children may therefore suffer little after the death of their fathers, as any services provided by the father can be taken over by other related males in the compound.

Additionally, the loss of the father may affect the investment decisions of other relatives, such as grandmothers and grandfathers, who may increase their investment to

compensate for the lack of the father (Winking, in press). For example, though illegitimate children tended to have higher mortality rates than legitimate children in historical Europe (providing indirect evidence for the importance of male support: van Poppel, 2000), there is some suggestion that kin support from maternal grandparents could alleviate the disadvantages of illegitimacy, indicating interactions between the presence of the father and extended kin (Blaikie, 1998).

The facultative and time-varying nature of paternal investment makes adaptive sense given that child mortality is probably not the most important determinant of male reproductive success. Under some circumstances at least, men are likely to achieve significantly greater gains in fitness by directing their efforts towards gaining additional mates rather than investing in existing children. In polygynous societies, men have the option of spending their resources on attracting additional wives. This could account for some of the variation: for example, the absence of a father effect in polygynous Gambians or Kipsigis (Borgerhoff Mulder, in press; Sear et al., 2002), but a significant positive effect of fathers in monogamous, historical Quebec (Beise, 2005). Even if successfully polygynous men were inclined to provide for children, they would find it rather difficult to provision all of their offspring; men with multiple wives can father considerable numbers of children (the most reproductively successful man in our Gambian population had 36 children). We conclude that a full investigation of how much fathers matter requires analysing the effects of fathers on all components of reproductive success; investigating how such investment may vary over the life-cycle of both fathers and children; and how such investment varies according to specific environmental conditions.

### 3.3 Grandmothers and child mortality

If the impact of fathers on the survival of children is variable, is there any evidence that the impact of grandmothers is more consistently beneficial? The results presented in Tables 2a and 2b suggest that grandmothers may be more reliable sources of help than fathers, though they do not have universally positive effects on child survival. There are also some differences between maternal and paternal grandmothers, with maternal grandmothers appearing to be somewhat more reliable helpers than paternal grandmothers. In total, maternal grandmothers improved child survival in 69% of cases (nine of 13 studies); the proportion is similar if only statistically valid studies are taken into account (seven of 11: 64%). Paternal grandmothers seem to be somewhat less consistent helpers if all studies are considered: they improve child survival in 53% of cases (nine of 17), though the proportion rises to 60% of statistically valid studies. Tables 2 and 3 also highlight that kin are not necessarily always beneficial to children: in two studies there was a detrimental effect of paternal grandmothers on child survival, and in one case the maternal grandmother had a detrimental effect (though this latter dataset did not include grandmaternal effects for children whose mothers had died, and in such cases anecdotal evidence suggested maternal grandmothers play a crucial role: Sear, 2006). This greater variability in the effects of paternal grandmothers may be in part explained by the greater age of paternal than maternal grandmothers, due to females reproducing earlier than males (though maternal age, and sometimes age of grandparents, is controlled for in those studies in Table 2a). Or it may reflect their lower level of genetic relatedness to their patrilineal descendants (due to paternity uncertainty). Separating out the effects of maternal and paternal relatives on female fitness is clearly important, as maternal and paternal kin may therefore differ in both their ability and inclination to invest in children. This may explain why two of the three studies

which have not separated out the effects of maternal from paternal grandmothers have found no effect.

A closer inspection of the timing of these grandmaternal effects suggests evidence that maternal and paternal relatives have different roles to play in the lives of mothers and children. In some populations, maternal grandmothers appear to have the strongest effect around the age of weaning (Beise, 2002, 2005; Sear et al., 2002). Weaning is a dangerous time for children. It increases their exposure to pathogens in food, and is often associated with the arrival of a younger sibling, when mothers divert their attention away from weaned children and to their new babies. Maternal grandmothers may be stepping in to protect children from the dangers associated with this stage of childhood (see Thompson & Rahman, 1967 for an example of this in the Gambia). Paternal grandmothers, in contrast, often appear to have the strongest effect (whether beneficial or detrimental) during the first month or year of a child's life (Beise, 2002, 2005; Kemkes-Grottenthaler, 2005). Mortality in this period is less dependent on exogenous causes (such as quality of care received) and more dependent on endogenous causes (such as low birthweight: Mosley & Chen, 1984). Birthweight is correlated with the condition of the mother during pregnancy (Andersson & Bergstrom, 1997; Kirchengast & Hartmann, 1998). Paternal grandmothers may therefore affect child mortality by affecting the condition of the mother during pregnancy. This effect may be beneficial (perhaps by helping out with domestic or productive tasks) or detrimental (stress and harassment may lead to worse maternal condition and higher neonatal mortality rates). The pathways through which maternal and paternal grandmothers affect child survival may therefore be somewhat different: the former help out with direct childcare; the latter affect the condition of the mother, and thereby the child, by helpful (or occasionally harmful) behaviour during pregnancy.

Most of the studies in this review have only used correlational evidence to infer helping behaviour from kin, but Gibson & Mace (2005) also collected time budget data to establish what relatives were actually doing for one another. This analysis provides further support for the suggestion that maternal and paternal relatives perform different functions in women's lives. Maternal grandmothers were found to help women out with heavy domestic tasks, thus freeing mothers for childcare. Paternal grandmothers, on the other hand, were more likely to help women with agricultural work, an activity from which they may gain a direct benefit (i.e. a share in the harvest).

### **3.4 What about grandfathers and other adult kin?**

Grandfathers are much less important to children. In 10 of 12 cases (83%), maternal grandfathers had no effect on child survival, though a positive effect in the remaining two cases. Paternal grandfathers had no effect in six of 12 cases (50%); a negative effect in three (25%) and a positive effect in three cases (25%). However, even where associations are found between grandfathers and child survival they tend to be of borderline statistical significance. In four of the six cases where paternal grandfathers had an impact on child survival, for example, the effect was borderline or applied only to female children.

Data on the effects of related reproductive-aged adults on child survival (apart from parents, such as aunts and uncles) is relatively scarce. The little evidence available suggests the effects of such relatives are very mixed (see the 'Other effects and notes' columns in Tables 2a and 2b for details). The children of Kipsigis agropastoralists in Kenya do better if they have either paternal or maternal uncles (Borgerhoff Mulder, in press). Chewa children in Malawi have lower survival if maternal aunts are present, but only in households in which

women own resources. In the minority of households in which men own resources, maternal aunts protect against child mortality (Sear, 2007). Venetian children apparently neither gain nor suffer from aunts or uncles (but neither maternal nor paternal, nor aunts and uncles were distinguished: Derosas, 2002). Similarly, aunts and uncles have no impact on Ache child (though maternal and paternal relatives were not distinguished: Hill & Hurtado, 1996) In historical China, the presence of reproductive aged females (usually paternal aunts) increased mortality for motherless children (Campbell & Lee, 2002). 19<sup>th</sup> century Mormon children benefited from maternal uncles and either kind of aunt (Heath, 2003). Reproductive-aged adults may be in a position to help one another with childcare, domestic tasks or productive activities, but also may either be too concerned with the well-being of their own small children, or actively in competition with each other for resources to be consistently beneficial. In a study of childcare arrangements in Efe hunter-gatherers, Ivey (2000) found that children were frequently looked after by individuals other than their mothers but these allocarers were rarely other women who had nursing infants of their own. Data from historical studies do however suggest that one category of reproductive-aged women may be beneficial for child survival: stepmothers. Despite numerous folk tales warning of the dangers of the wicked stepmother, both Andersson et al. (1996) and Campbell and Lee (2002) found that children with stepmothers had similar risks of dying to those children who still had their own mothers, which were considerably lower than the mortality risks of children without either mothers or stepmothers. Such analyses need to be interpreted with care, as children with stepmothers will be older and have experienced the death of their mothers further in the past than most motherless children. But if this is not a statistical artifact, such philanthropic behaviour on the part of step-mothers may be a form of mating effort, as has been suggested for step-parental behaviour in non-human animals (Rohwer et al., 1999).

### 3.5 Helpers at the nest

Rather few studies have investigated the effect of potential sibling ‘helpers at the nest’ on child survival, despite the widespread observation that the labour of older children is used by parents both for domestic work (including childcare) and productive activities (Borgerhoff Mulder & Milton, 1985; Cain, 1977; Kramer, 2002, 2005; Weisner & Gallimore, 1977). The effects of older siblings, however, are complicated by competitive relationships. Several studies have found that older siblings increase, rather than decrease, the risk of death for children (e.g. Das Gupta, 1987; Kemkes, 2006; Muhuri & Preston, 1991). These effects are usually interpreted as parental manipulation of the size and sex composition of their families for optimal allocation of limited family resources. Here, we only present studies which have investigated the effect of older siblings who are potential helpers, rather than competitors, by restricting the analysis to those children several years older than the focal child (at least three years older, and often more, depending on the study). Restricting the analysis in this way is not a perfect method of identifying the effect of helpers at the nest, and will bias the sample in other ways, e.g. it will include a disproportionate number of later born children, and exclude firstborns. But all of the studies which investigated helping at the nest used some statistical controls, which should reduce, though not eliminate, potentially confounding factors. Only six studies analysed helping at the nest, but five of these studies find potential helpers have a positive effect on child survival. The sixth study only investigated the effects of adult siblings, who may have been occupied with children of their own. In some cases this positive effect is specific to older sisters, suggesting the domestic responsibilities of juvenile girls (including childcare) are important, but in other cases the sex of helpers does not matter, suggesting all activities contributed by pre-reproductives are beneficial.

### 3.6 Confounding effects

Some of the studies in the sample found that kin effects are not straightforward. In a few populations, the effect of a particular category of kin was only seen for children of one sex. Mothers themselves are known to invest differentially in children according to sex and birth order. Other kin may mirror the investment decisions of mothers, by investing in similarly favoured children. The reproductive interests of kin are not necessarily identical to those of the mother, however. Sorenson Jamison et al. (2002) highlight the possibility that paternal grandmothers in Japan are influenced by concerns of lineage, which means that certain children (such as later born boys who may be unwelcome competitors for favoured male heirs) are particularly disadvantaged, whereas other grandchildren may be supported. Such sex-specific and birth order biases, which are found in a number of wealth-inheriting societies, would confound attempts to label individual kin relationships as always positive or negative for child survival. Such grandmothers would, nonetheless, be attempting to promote their lineage, albeit at the expense of certain unfortunate grandchildren.

Availability of resources also seems to alter kin effects. Both Borgerhoff Mulder (in press) and Leonetti et al. (2004) found interactions between kin effects and wealth. In the Kipsigis, paternal uncles are most important for buffering rich children against mortality but maternal uncles are more important in poor families (Borgerhoff Mulder, in press). In India, husbands were more likely to help women out in poorer households (Leonetti et al., 2004). In the latter study, the condition of the mother also mattered. There was a tendency for men to be more helpful to women with fewer resources, both economic and physiological: shorter women were more likely to be helped by husbands. There were also interactions between help given by husbands and grandmothers (more help from grandmothers correlated with less help from husbands). These complications to the story of kin help suggest that help from any

category of kin may be facultative to some extent, depending on other factors such as the available resources, the mother's ability to rear children and the presence of other kin.

A final word about confounding effects. A common criticism of studies which find a correlation between the survival of a particular relative and child survival is that these effects might simply be due to shared genes or environment, i.e. certain children come from 'healthy' families where both they and their relatives have good survival prospects, and others come from 'unhealthy' families where their own survival chances are low, as is the probability that their relatives have survived long enough to help care for them. While such explanations cannot entirely be ruled out, the results presented in Tables 1 and 2 suggest that shared genes or environment is unlikely to be the full explanation in all cases. For example, if such confounding effects were important we would expect to see positive relationships between children and all categories of kin. Instead we see considerable variation between relatives and between populations in which kin are important for child survival. The effects of kin are also often dependent on the age of the child. Again, if shared genes or environment were responsible for these results then the survival of kin should be correlated with child survival throughout the child's life. Thirdly, several studies have controlled for shared environment between relatives by including statistical controls for economic factors (e.g. Borgerhoff Mulder, in press; Gibson & Mace, 2005; Leonetti et al., 2005), or by using hierarchical models which control for family-level effects (e.g. Beise, 2002; Borgerhoff Mulder, in press; Sear et al., 2002; Tymicki, 2006). Significant kin effects are still seen even using such controls. Finally, the authors of these studies are frequently aware of this potential confound and have often used additional analysis or ethnographic evidence to interpret the results of their correlational analysis, to provide assurances that these results are unlikely to be entirely due to shared genes or environment (see, e.g., Sear et al. in press).

488

## 489   **4.0   Discussion**

### 490   **4.1   Evolution and the human family**

491           What does this review tell us about the evolution of the human family? Clearly, there  
492   is a problem using data on current populations to infer anything about evolutionary history.  
493   Certainly the study of a single society tells us little about evolution of a particular trait. In the  
494   Gambia, we found positive effects of maternal grandmothers and no effect of fathers on child  
495   survival, but this does not constitute strong evidence in favour of the importance of older  
496   women and the unimportance of men in the human family. These results could have arisen  
497   due to some peculiarities of Gambian ecology. Cross-cultural analysis is essential to  
498   determine which traits are common across societies and which vary according to  
499   environmental conditions (see e.g. Walker et al., 2006 for an example on growth). This  
500   review offers hints about which features of the human family may have been common  
501   throughout our evolutionary history, and which are adaptations to local environments. We  
502   conclude from this review that kin support in rearing offspring does appear to be a human  
503   universal. Support from maternal kin (especially grandmothers) may perhaps be more reliable  
504   than that from paternal kin, though no category of kin is universally beneficial. Support from  
505   fathers for young children also appears to be facultative, and dependent on ecological  
506   conditions.

507

508           But does even this cross-cultural review tell us anything about the *evolution* of the  
509   human family? This review covers a variety of human cultures, but examining the impact of  
510   relatives on child mortality is a data intensive exercise. This means that the dataset has  
511   relatively few hunter-gatherers, and is biased towards those who made at least some of their

512 living from farming. Is it possible that throughout most of our history we have lived in  
513 relatively stable (perhaps nuclear) families where fathers assume more importance in  
514 provisioning children, or even where mothers were better able to provision their children  
515 alone? The variation we see among extant populations may be, at least in part, a response to a  
516 shift in subsistence and demographic patterns to a set of conditions which make helping by  
517 extended kin more favourable. For example, if agricultural populations have higher fertility  
518 and lower adult mortality than hunter-gatherers, this might make kin (such as grandmothers  
519 and older children) both available and necessary as helpers. Draper & Harpending (1987)  
520 have suggested that paternal involvement and sibling care may differ systematically between  
521 foraging and farming communities, with father involvement much more common among  
522 foragers and sibling care more frequent among farmers (see also Hewlett, 1991). Kaplan &  
523 Lancaster (2003) have also argued that shifts in subsistence strategy during human history  
524 have been accompanied by shifts in optimal family structure. In particular, they assert that the  
525 move from foraging to horticulture and agriculture was accompanied by a significant  
526 reduction in the importance of male provisioning to children.

527

528       If there are such systematic differences in the family structures of farmers and  
529 foragers, then our sample may well overestimate or underestimate the importance of certain  
530 relatives. However, it seems unlikely to us that one particular family structure has been of  
531 paramount importance throughout human history. Existing hunter-gatherer populations are  
532 hardly uniform in either their subsistence strategies or demographic patterns. Hunter-gatherer  
533 populations have, after all, been used to illustrate both the importance of fathers (Ache), and  
534 the importance of grandmothers (Hadza). This particular debate might reflect differences  
535 between Old World and New World foragers, since foragers in the Old World tend to rely  
536 relatively more on gathering and have lower male contributions to the diet than New World

foragers (Marlowe, 2005). There are also problems in using extant hunter-gatherer populations as models for past hunter-gatherers as many of the remaining hunter-gatherers occupy marginal environments unsuitable for farming activities (though this view has recently been questioned: Marlowe, 2005). This variability shown by hunter-gatherer populations is unlikely to have been of recent origin, given that recent estimates suggest hominins have had a wide geographical distribution (i.e. outside of Africa) for nearly 2 million years (Dennell & Roebroeks, 2005). If early hominids had a wide geographic distribution then they probably occupied a variety of different environments, with associated plasticity in behavioural characteristics.

It seems more parsimonious to us to assume that human family systems have always been somewhat flexible and responsive to ecological conditions, as are those of many other primates. After all, as Hrdy (2005) points out, relying exclusively on a single category of kin (such as fathers) seems a rather risky strategy, given the improbability that one particular relative will survive and be able to help throughout a woman's reproductive career.

## **4.2 Evolution of human life history**

We introduced this paper by describing the unusual features of human female life history – late puberty, short birth spacing and menopause. Does this review tell us anything important about the evolution of human female life history characteristics? We have found unmistakable support for the hypothesis that women receive help from kin in raising children in extant populations, but can we infer from this that characteristics of human life history can be explained by the cooperative nature of human reproduction? Again, it is difficult to draw conclusions about the evolution of a particular trait by examining existing populations. For example, grandmothers (of one kind or another) do appear to be almost universally beneficial

across societies in improving the fitness of their relatives: in all 12 studies which investigated the impact of both maternal and paternal grandmothers, as least one kind of grandmother was beneficial for child survival. This provides some support for the grandmother hypothesis for menopause, but we still cannot be entirely certain that menopause evolved because of its fitness benefits. It may be that grandmothers invest in their grandchildren because they are unable to continue having children of their own, and investing in grandchildren is better than investing in nothing at all. Rather than relying solely on statistical investigations of patterns of behaviour in modern populations, mathematical modelling may be necessary to get at the evolution of particular traits, by quantitatively testing whether a particular trait is likely to have evolved given a set of parameters.

Most attempts to build quantitative models in which women can compensate for lost fertility in later life through enhancing the fitness of children and grandchildren have failed to find fitness benefits sufficiently large to favour menopause at 50 (Grainger & Beise, 2004; Hill & Hurtado, 1991; Rogers, 1993). Shanley & Kirkwood (2001) argue that menopause at a slightly older age could be favoured if a range of selective forces are combined, including an increase in maternal mortality with age, as well as grandmaternal effects both on grandchild survival and on their daughters' fertility (and these latter effects need to be large). When parameterising this model with data from the Gambia (Shanley et al. in prep), we find that maternal and grandmaternal effects on child survival are particularly important, and parental contributions to daughters' fertility are less important. But again, realistic parameter values suggest a late age menopause is adaptive, which implies that some important effect may still be missing from the model.

That these quantitative analyses suggest marginal, if any, benefits of menopause at 50, has contributed to a belief that grandparental and parental care are a significant selective force on human longevity, but not necessarily on the timing of menopause (Hawkes et al., 1998). Recent work has focussed on modelling the mortality schedules and aging patterns of our species, rather than a specific component of human life history such as menopause. These models have suggested that many of the peculiarities of human life history, including a long juvenile period, long lifespan and postreproductive life, may hinge on intergenerational transfers in general (not specifically those from grandmothers, but including all transfers from older to younger individuals: Kaplan & Robson, 2002; Lee, 2003; Pavard et al., 2007). The mathematical framework needed to address these problems continues to develop. Such models would also benefit from more information on the parameters needed to inform these models: effect sizes for kin help across a number of different populations would illustrate the relative importance of mothers, fathers and grandmothers. Whether elaborations of these models using realistic human parameters can explain menopause, as well as other human life history characteristics, better than existing models awaits further analysis.

### **4.3 Next steps**

This review has of necessity been a fairly crude analysis of the effects of kin on child mortality: we have simply presented numerical data on the number of populations which have found, or failed to find, an effect of various relatives on child survival. We have attempted no meta-analysis of the data presented here, because of the considerable variation in statistical methodology (or lack of it) used in these studies. Even in those studies which do calculate effect sizes, the magnitude of the effects cannot be compared directly for a number of reasons, including differences in the age of children being studied, in which confounding factors were controlled, and whether interactions between the effect and child's age were

611 included in the models. Additionally, not all studies in this sample can be considered  
612 independent data points, since a few come from similar populations. Nevertheless, we believe  
613 this is a useful exercise as a first step in systematically determining which kin are helpful to  
614 mothers in raising children and under which circumstances these kin help. This review has  
615 found some commonalities but also substantial variation between populations in which kin  
616 help women raise children. The next step is to explain this variation within an evolutionary  
617 ecological framework. This could involve a meta-analysis of those studies which have  
618 investigated this issue, testing hypotheses about the circumstances under which particular kin  
619 help, preferably using appropriately phylogenetically controlled methods (Mace & Pagel,  
620 1994), though this is unlikely to be practical until more studies can be collated on the effects  
621 of kin on child survival. We suggest the following, by no means exhaustive, list of potential  
622 factors may affect the level of help offered by particular relatives. (1) Subsistence strategy,  
623 which may affect: (a) the degree to which certain kin may help (e.g. children may be  
624 economically productive in some agricultural societies, but less so hunter-gatherer  
625 communities); and (b) the division of labour between sexes, which affects what kind of help  
626 kin can provide and the extent to which help is necessary. (2) Demography: the probability of  
627 having a particular relative around to help depends on a number of demographic factors such  
628 as sex-specific mortality rates, age-specific fertility rates and age difference between spouses.  
629 (3) Marriage and mating systems (which will also be linked to demography through the  
630 operational sex ratio): polygynous men are likely to find it difficult to invest in children from  
631 several mothers, and will also have alternative mating opportunities which make mating  
632 effort more productive than parental effort. (4) Resource availability: which may affect the  
633 demography and marriage patterns of a population. (5) Inheritance patterns: which may result  
634 in selective helping of certain children. (6) Residence patterns: which will affect which kin  
635 are most available for help.

636

637           This study has only examined statistical correlations between the survival of kin and  
638 survival of children. While we have attempted to separate out studies which are likely to have  
639 demonstrated genuine correlations from those which have not adequately controlled for  
640 potentially confounding factors, even those studies which have used appropriate statistical  
641 analysis have not demonstrated a *causal* relationship between the presence of kin and the  
642 survival of children. A better understanding of the pathways by which kin help would  
643 improve our understanding of why these associations are found (and provide reassurance  
644 these effects are not merely statistical artifacts). The studies that are presented here suggest  
645 that the pathways through which kin influence reproductive success may well differ between  
646 relatives. Men and women appear to help in different ways, because of sexual division of  
647 labour within societies (e.g. help in direct childcare is much more likely to come from female  
648 kin than male kin). There also appear to be differences in the kinds of help offered by  
649 maternal and paternal kin in their helping behaviour (and not only in the frequency with  
650 which they offer help: Beise, 2005; Gibson & Mace, 2005). Pathways may also be more  
651 variable for fathers than for other kin. Fathers can potentially provide a variety of services to  
652 children including provisioning with food, providing protection from other males, childcare,  
653 and other social benefits. Female kin tend to confine their roles to lifting energetic burdens  
654 from women by helping out with childcare, domestic and subsistence activities. This review  
655 has also highlighted that not all kin are beneficial. Suggestions for the detrimental effects of  
656 relatives on child survival have included competition for resources (Campbell & Lee, 1996)  
657 and conflicting interests between women and their husband's kin (Beise, 2002; Volland &  
658 Beise, 2005). These results suggest that any models which attempt to investigate the  
659 evolution of certain life history traits need to take into account differences between maternal  
660 and paternal kin, as well as potential conflicts between relatives.

661

#### 662 **4.4 Relevance to current family policy debates**

663 Finally, we conclude with a brief discussion of the relevance of such evolutionary  
664 analysis to family policy. There is a tendency for policymakers in Western countries to  
665 believe that the nuclear family model is most beneficial for individuals, children and society,  
666 and that the decline in marriage and increase in divorce and single motherhood in recent  
667 years marks an unprecedented decline in the family in human history (McDonald, 2000). This  
668 nuclear family model also usually includes a rather rigid view of the division of labour within  
669 families, with mothers primarily concerned with childcare and the domestic sphere, and  
670 fathers responsible for economic provisioning. Policy theorists have claimed that all welfare  
671 states were initially predicated on the nuclear family model, and most still subscribe to some  
672 degree to this model (Lewis, 1992; Sommestad, 1997). There is an enormous literature  
673 arguing that father absence has detrimental consequences for children (see Sigle-Rushton &  
674 McLanahan, 2004 for a review), reinforcing the view that marriage is good for children,  
675 divorce is bad, and that children should grow up in a home with both biological parents. But  
676 this review shows that the human family is clearly a diverse entity, and that the nuclear  
677 family system may not be the normative solution to the problem of raising children in all  
678 circumstances (though it may be in others).

679

680 What is clear from this review is that this nuclear model is a rather unusual family  
681 system in extant populations, which gives us little reason to assume that it has been common  
682 throughout our evolutionary history. The three features which make this nuclear family  
683 model somewhat unusual are: that women are expected to care for children alone; that  
684 women are not expected to contribute any productive labour; and the vital role that fathers  
685 play in the economic support of the family. The studies cited here demonstrate that mothers

do not raise their children alone in many societies, but receive substantial help from others, so that it is not at all unusual for children to receive care from other kin and group members. It is also extremely unusual for women to take no part in productive activities. Hewlett, in a table titled 'the myth of the male breadwinner', tabulates the contribution of women to the family diet from 90 societies worldwide and observes that in half the societies the breadwinner role was shared roughly equally between men and women, and that the number of societies in which men were the main breadwinners was equalled by the number of societies in which females contributed the majority of the family diet (Hewlett, 2000). Not dissimilar results are seen if only hunter-gatherers are considered (Hewlett, 1991; Marlowe, 2005). This both questions the lack of female involvement in production, and also the role that fathers play within the family. While fathers may well be important to their offspring, exactly what they do to support their children, and how this investment is patterned across the life-cycle, is likely to vary substantially both between and within societies, according to the level of available resources, degree of paternity certainty and other factors. Additionally, the lack of a substantial father effect on child mortality in many societies suggests that when fathers are absent, other relatives or group members may be able to compensate for the loss of the father. These observations of considerable variation in optimal family structure suggest it might be useful for policymakers to take a slightly less rigid approach when considering what is the best environment to raise a child .

This does raise the question of exactly how such evolutionary analyses can be used to inform family policy, if at all. For example, knowledge that the best kind of family to raise a child can take several forms may not be necessarily useful to policymakers trying to formulate policies at a national level. A recent attempt to use evolutionary psychology to inform family policy appeared to conclude that evolutionary approaches are useful because

they allow us to understand better the preferences of individuals, so that social policy can be directed towards fulfilling these preferences (Browne, 2002). However, an evolutionary perspective also tells us that the preferences of individuals may be well in conflict: the preferences of men may not coincide with the preferences of women; the preferences of children may not coincide with those of parents; and the preferences of the family may very well be in conflict with those of institutions such as employers, governments, etc. Evolutionary analyses can be used to gain a better understanding of human behaviour, but cannot be used to provide easy policy solutions.

## **5.0 Conclusion**

We have presented evidence that human children benefit from an extended family and that kin support can enhance female reproductive success. There are several studies focussing on components of reproductive success that further support this view, but we narrowed our discussion here to those that could identify a kin effect on child survival, an unambiguous determinant of reproductive success, so that we could unpick differing influences within the family. This analysis reveals some commonalities and some differences in kin help. A consistency across studies is that at least one relative is beneficial in almost all populations, suggesting that we are evolved to raise children as an extended family enterprise. Maternal grandmothers tend to improve child survival, as do elder sibling ‘helpers-at-the-nest’. Paternal grandmothers are frequently beneficial, but show rather more variation than maternal grandmothers in their effects on child survival. Fathers’ contributions to child survival appear to be surprising small. This review has also highlighted that kin interactions are not always beneficial, and that the presence of certain kin may occasionally be harmful for child

734 survival. A systematic analysis of what causes this variation in kin support should be the next  
735 step in furthering our understanding of the human family.

736

**Table 1a: Studies of the effect of the mother on child survival**

Population	Authors	Effect of mothers	Age of children studied	Timing of mother effect	%age surviving mother's death	Notes
Nepal (Sarlahi) 1994-97	Katz et al., 2003	+	0-24 weeks	0-24 weeks <sup>1</sup>	35%	Maternal deaths <sup>2</sup> only considered. Effect size increased with age of infant.
Caribbean (St Barthélemy) 1878-1976	Brittain, 1992	+	0-1 yr			%age survival to 1 yr after mother's death in first year
Gambia (4 villages) 1950-74	Sear et al., 2000; 2002	+	0-5 yrs	< 2 yrs only		Nutritional status also lower without mothers
Kenya (Kipsigis) 1945-90	Borgerhoff Mulder, in press	+	0-5 yrs			
Burkina Faso (Nouna) 1992-99	Becher et al., 2004	+	0-5 yrs	0-5 yrs	50%	%age survival in follow-up period (0-5 yrs) after mother's death in first year. Effect weakens with child's age
Sub-Saharan Africa <sup>3</sup> 1980s-2000	Zaba et al., 2005	+	0-5 yrs	<2 yrs only		Effect limited to first yr after mother's death. Relationship holds for HIV –ve children
Canada (Quebec) 1680-1750	Beise, 2005	+	0-5 yrs	0-5 yrs		Effect weakens with child's age
Poland (Bejsce) 1737-1968	Tymicki, 2006	+	0-5 yrs	0-5 yrs		
Guinea-Bissau 1990-98	Masmas et al., 2004	+	0-8 yrs	<2 yrs only		Low HIV prevalence, so effect not due to mother-to-child-transmission of HIV
Paraguay (Ache) 1890-1971	Hill & Hurtado, 1996	+	0-9 yrs	0-9 yrs		Weak evidence that effect declines with child's age (interaction between mother and child's age sig at p=0.09)
Netherlands (Woerden) 1850-1930	Beekink et al., 1999; 2002	+	0-12 yrs	<6 mths / 0-12 yrs		1999 paper suggests effect only seen <6 mths; 2002 paper effect seen up to age 12, though weakens with child's age
Italy (Tuscany) 1819-59	Breschi & Manfredini, 2002	+	0-12 yrs			
Canada (Quebec) 1625-1759	Pavard et al., 2005	+	0-15 yrs	0-15 yrs	40%	Effect weakens with child's age. Neonates excluded.
Sweden (Sundsvall) 1800-1895	Andersson et al., 1996	+	0-15 yrs	<1 yr only		Effect stronger on girls after age 3 yrs
Japan (Central) 1671-1871	Sorenson Jamison et al., 2002	+	1-16 yrs			%age survival to 15 yrs after mother's death in first year
China (NE) 1774-1873	Campbell & Lee, 1996, 2002	+	~1-15 yrs	Strongest ~6-10 yrs		Effect stronger for boys (but seen in all children)
						Timing of effect only tested for boys

<sup>1</sup> Excluded from discussion of timing effects since only very young children included in the study

<sup>2</sup> Definition of maternal death may differ between studies but broadly refers to death due to childbirth

<sup>3</sup> Pooled data from 3 cohort studies in Tanzania, Malawi and Uganda

**Table 1b: Supplementary data on the effect of mothers on child survival (not statistically controlled for confounding factors)**

Population	Authors	Effect of mothers	Age of children studied	Timing of effect	%age surviving mother's death	Notes
US (New York State) 1936-38	Yerushalmy et al., 1940	+	0-1 mth			Maternal deaths only considered
Bangladesh (Matlab) 1967-70	Chen et al., 1974	+	0-1 yr		5%	%age survival to 1 year after maternal death
Bangladesh (Matlab) 1976-85	Koenig et al., 1988	+	0-1 yr		25.9%	%age survival to 1 year after maternal death. Deaths among older siblings <3 yrs not affected by maternal death
US (8 cities) 1920s	Woodbury, 1926	+	0-1 yr		40%	%age survival to 1 yr after mother's death in first month
Tanzania (Hadza) 1980s-90s	Blurton Jones et al., 1996	+	0-5 yrs			
Uganda (Rakai) 1994-2000	Bishai et al., 2003	+	0-6 yrs			Effect holds for HIV –ve children
Bangladesh (Matlab) 1983-85	Over et al., 1992	+	0-9 yrs			Effect substantially stronger for girls
Spain (Aranjuez) 1870-1950	Reher & González-Quiñones, 2003	+	0-9 yrs	<2 yrs only		Effect strongest for boys in neonatal period; girls at older ages. Effect increases over calendar time. Nutritional status also lower without mothers
Italy (Venice) 1850-69	Derosas, 2002	+	0-10 yrs			
Germany (Ostfriesland) 1668-1879	Voland, 1988	+	0-15 yrs		48.5%	%age survival to 15 yrs after loss of mother in first year
Sweden (7 parishes) 19 <sup>th</sup> C	Högberg & Broström, 1985	+	0-15 yrs	<5 yrs only	1.6%, 3%, 13%	%age survival to age 5 if child lost mother at birth, during first year and between 1-5 yrs respectively
UK (Cambridgeshire) 1770-1861	Ragsdale, 2004	+	0-15 yrs			Loss of mother within 2 yrs of birth of child

**Table 2a: Studies of the effects of fathers, grandparents and older siblings on child survival**

Population	Authors	Age of child (yrs)	Effect of fathers	Effect of maternal gms	Effect of paternal gms	Effect of maternal gfs	Effect of paternal gfs	Effect of older sibs	Other effects and notes
Gambia (4 villages) 1950-74	Sear et al., 2000; 2002	0-5	none	+	none	none	none	+	Elder sisters only increase survival (not brothers), and only at 24-59 mths; divorce - Fathers improve survival 1-23 mths; pgms in first month; mgms 12-35 mths; mgfs 36-59 mths; pgfs 36-59 mths but only for girls Mgms borderline, but sig at p<0.05 for girls only; mat aunts – in families where women own resources, + where men do; divorce - Mat and pat uncles +; pgm and mat uncle effects stronger in poor households; pat uncle effect stronger in rich households All grandparental effects seen only in first year; father effect seen at all ages Mgm effect borderline; pgm effect only seen for boys; pgfs only for girls Pgm effect only in first year
Canada (Quebec) 1680-1750	Beise, 2005	0-5	+	+	+	+	(+)	+	
Malawi (Chewa) 1992-1997	Sear, 2007	0-5	none	(-)	(+)	none	none	+	
Kenya (Kipsigis) 1945-90	Borgerhoff Mulder, in press	0-5	none	none	+	none	none		
Poland (Bejsce) 1737-1968	Tymicki, 2006	0-5	+	+	+	+	+		
Japan (Central) 1671-1871	Sorenson Jamison et al., 2002	1-16	none	(+)	(-)	none	(-)		
Germany (Ludwigshafen) 1700-1899	Kemkes-Grottenthaler, 2005	0-2		none	+	none	-		
Ethiopia (Oromo) 1993-2003	Gibson, in preparation; Gibson & Mace, 2005	0-5	+/-	(+)	(+)	none	none		
Germany (Krummhörn) 1720-1874	Beise, 2002; Voland & Beise, 2002	0-5		+	-	none	none		
Italy (Venice) 1850-69	Derosas, 2002	0-10		none	(+)	none	(-)		
India (Khasi) 1980-2000	Leonetti et al., 2004, 2005	0-10	none	+					Pgm effect only seen in orphaned children; pgf effect only <1yr; both effects borderline; no effect aunts/uncles Mgm effect seen in first yr only
Bolivia (Tsimane) 1930s-2000s	Winking et al., 2006	0-10	none						Child's risk of murder was increased if father was dead, but not overall mortality Death of father increased risk of emigration
Italy (Tuscany) 1819-59	Breschi & Manfredini, 2002	0-12	none						

Sweden (Sundsvall) 1800-95	Andersson et al., 1996	0-15	none						Stepmother +
Japan (NE) 1716-1870	Tsuya & Kurosu, 2002	2-14	+						
Netherlands (Woerden) 1850-1930	Beekink et al., 1999, 2002	0-12	(+)						Fathers only had effect within 1 mth of their deaths
India (Bengali) 1980-2000	Leonetti et al., 2005	0-10			+				Pgm effect only seen in children 1-9 yrs
India (Uttar Pradesh) 1990-3	Griffiths et al., 2001	0-2			+				Pgm effect only in first mth
India (Tamil Nadu) 1990-3	Griffiths et al., 2001	0-2			none				
India (Maharashtra) 1990-3	Griffiths et al., 2001	0-2			none				
NE India (8 states) 1994-9	Ladusingh & Singh, 2006	0-5			none				
Bolivia (Aymara) 1960s-90s	Crognier et al., 2002	0-15						+	Elder brothers and sisters improve survival
Morocco (Berber) 1930-80	Crognier et al., 2001	0-15						+	Elder brothers and sisters improve survival
Finland (5 communities) 18 <sup>th</sup> & 19 <sup>th</sup> C	Lahdenpera et al., 2004	0-15		(+)					Pat and mat gms not distinguished; effect only seen 2-15 yrs, and only for gms <60 yrs old
Paraguay (Ache) 1890-1971	Hill & Hurtado, 1996	0-9	+	none		none		none	Mat and pat grandparents not distinguished; elder sibs only include adult sibs; no effect aunts or uncles
China (NE) 1774-1873	Campbell & Lee, 1996, 2002	~1-15	(+)	none		-			Father effect only in girls; pat and mat grandparents not distinguished; presence of 'adult women' increases mortality for boys if no mother or stepmother present; stepmother +

**Table 2b: Supplementary data on the effects of fathers, grandparents and older siblings on child survival (not statistically controlled for confounding factors)**

Population	Authors	Age of child (yrs)	Effect of fathers	Effect of maternal gms	Effect of paternal gms	Effect of maternal gfs	Effect of paternal gfs	Effect of older siblings	Other effects and notes
UK (Cambridgeshire) 1770-1861	Ragsdale, 2004	0-15	none	+	none	none	none		
Utah (Mormons) 19 <sup>th</sup> century	Heath, 2003	0-1		+	none	none	(+)		Pgf effect borderline; mat aunts, mat uncles and pat aunts +
Tanzania (Hadza) 1980s-90s	Blurton Jones et al., 2000	0-5	none						Father absence tested (including death and desertion)
Venezuela (Hiwi) ~1980s	Hurtado & Hill, 1992	0-5	none						Father absence tested (including death and divorce)
Uganda (Rakai) 1994-2000	Bishai et al., 2003	0-6	none						
Bangladesh (Matlab) 1983-85	Over et al., 1992	0-9	none						
Spain (Aranjuez) 1870-1950	Reher & González-Quiñones, 2003	0-9	none						Fathers improve nutritional status
Italy (Venice) 1850-69	Derosas, 2002	0-10	none						

**Table 3: summary of kin effects on child survival (figures in brackets represent percentages)**

	Statistically valid				Supplementary				Total			
	Number of studies	+ve effect	-ve effect	No effect	Number of studies	+ve effect	-ve effect	No effect	Number of studies	+ve effect	-ve effect	No effect
<b>Mothers</b>	16	16 (100)	0	0	12	12 (100)	0	0	28	28 (100)	0	0
<b>Fathers<sup>4</sup></b>	15	7 (47)	1 (7)	8 (53)	7	0	0	7 (100)	22	7 (32)	1 (4)	15 (68)
<b>Maternal gms</b>	11	7 (64)	1 (9)	3 (27)	2	2 (100)	0	0	13	9 (69)	1 (8)	3 (23)
<b>Paternal gms</b>	15	9 (60)	2 (13)	4 (27)	2	0	0	2 (100)	17	9 (53)	2 (12)	6 (35)
<b>Non-specific gms</b>	3	1 (33)	0	2 (67)	0	0	0	0	3	1 (33)	0	2 (67)
<b>Maternal gfs</b>	10	2 (20)	0	8 (80)	2	0	0	2 (100)	12	2 (17)	0	10 (83)
<b>Paternal gfs</b>	10	2 (20)	3 (30)	5 (50)	2	1 (50)	0	1 (50)	12	3 (25)	3 (25)	6 (50)
<b>Non-specific gfs</b>	2	0	1 (50)	1 (50)	0	0	0	0	2	0	1 (50)	1 (50)
<b>Older sibs</b>	6	5 (83)	0	1 (17)	0	0	0	0	6	5 (83)	0	1 (17)

<sup>4</sup> Percentages do not sum to 100 in this row because one study found a positive effect of fathers on the survival of sons and a negative effect on the survival of daughters
