Candidate declaration

I, Harriet Forbes, confirm that the work presented in this thesis is my own. Where information has been derived from other sources, I confirm that this has been indicated in the thesis.

Signed 
Thesis abstract

Background: Herpes zoster affects millions of people worldwide each year and many go on to suffer long-term pain, called postherpetic neuralgia (PHN). As zoster is common and PHN is difficult to treat, preventing zoster through vaccination is important. This thesis aims to better understand risk factors for zoster and PHN, in order to inform vaccination policy.

Methods: Three large observational studies were carried out using primary care data from the UK Clinical Practice Research Datalink and linked secondary care data from the Hospital Episodes Statistics. First, a matched case-control study quantified the effects of possible risk factors for zoster and explored whether their effects differed by age group. Second, a descriptive study looked at antiviral prescription patterns and patient characteristics associated with antiviral receipt after zoster diagnosis. Third, a cohort study assessed risk factors for PHN and investigated whether their effects were modified by antiviral use.

Results: The *case-control study of zoster risk factors* included 144,959 zoster patients and 549,336 controls and found an increased risk of zoster among patients with rheumatoid arthritis, systemic lupus erythematosus, inflammatory bowel disease, chronic obstructive pulmonary disease, asthma, chronic kidney disease, depression and type 1 diabetes; odds ratios ranged from 1.14 to 1.72. In general, the relative effects of these risk factors on zoster decreased with increasing age. In the *descriptive study of antiviral use*, of 142,216 zoster cases, only 58.1% received an antiviral prescription at zoster diagnosis. Antivirals were even under-prescribed among the immunosuppressed and older individuals, for whom guidelines recommend routine treatment. The *cohort study of PHN risk factors* identified 119,413 zoster patients, 5.8% of whom developed PHN. An increased risk of PHN was found among patients with rheumatoid arthritis, systemic lupus erythematosus, inflammatory bowel disease, chronic obstructive pulmonary disease, asthma, depression, type 2 diabetes, lower socioeconomic status, smoking and under- or overweight; odds ratios ranged from 1.13-1.82. Antiviral use was not associated with PHN risk overall. The *zoster case-control* and *PHN cohort study* showed that patients with severely immunosuppressive conditions were at greatest risk of both zoster and PHN.

Conclusions: A number of patient characteristics and comorbidities were associated with increased zoster and PHN risks. Patients at highest risk of zoster and PHN are those of older age and those with immunosuppression; currently, patients with immunosuppression are not eligible for vaccination, highlighting a need for alternative risk reduction strategies in this group. Low antiviral use at zoster diagnosis suggests treatment guidelines be revised to encourage greater use, especially among the immunosuppressed and older individuals who are recommended, but not routinely given, antivirals. Research on the cost-effectiveness of vaccinating patients with specific risk factors is needed.

Acknowledgements

Thank you to my supervisors, Sinéad Langan and Krishnan Bhaskaran, for their guidance and encouragement throughout. Thanks also to Sara Thomas, Liam Smeeth and Tim Clayton, for being part of my advisory committee. I would also like to thank Caroline Minassian, Helen McDonald, Jenni Quint and CALIBER for providing previously developed code lists, from which I was able to work from.

Role of the candidate, ethics and funding

The candidate was employed under an NIHR Clinician Scientist fellowship awarded to Sinéad Langan entitled, “The natural history and management of herpes zoster: the role of moderate immunosuppression from common diseases”. The research aims and objectives of this thesis grew from this fellowship, and from discussion between the candidate and supervisors. The candidate conceptualised the research and designed the studies, with input from supervisors. The candidate was responsible for all data management and analysis.

Regarding the research papers included in the thesis, the candidate did all the analysis and wrote the initial draft for all papers, and incorporated comments from co-authors in an iterative process.

This project was approved by the London School of Hygiene and Tropical Medicine Ethics Committee. The scientific protocol (included in full in appendix I) was by approved the Independent Scientific Advisory Committee for MHRA Database Research in April 2011, and further amendments were approved in May 2012 and April 2014.

This project was funded by the National Institute of Health Research, specifically an NIHR Clinician Scientist Fellowship (to Doctor Langan, grant number: NIHR/CS/010/014).The work was carried out independently of the funding bodies. The findings and conclusions in this report are those of the authors and do not necessarily represent the views of the UK Department of Health.

Chapter 1: Introduction

In this introductory chapter, I present a brief overview of herpes zoster and postherpetic neuralgia (PHN), followed by details of the zoster vaccine. The aims and objectives of the research are then described and an outline of the thesis is given.

1.1. Introducing herpes zoster and postherpetic neuralgia

1.1.1. Herpes zoster

1.1.1.1. Clinical presentation, diagnosis and treatment

Herpes zoster, more commonly known as shingles, typically presents as a painful, vesicular rash with a dermatomal distribution, preceded by tingling, itching or pain, termed prodromal pain. The rash usually abates within four weeks. Ophthalmic zoster occurs in approximately 10% of cases and occurs when the rash appears in the dermatome supplied by the ophthalmic nerve.[1]

Diagnosis of zoster is largely made clinically in primary care; hospitalization is rare, occurring in around 1 to 4% of cases.[2] Antiviral therapy is recommended for patients deemed at risk of severe zoster, including all patients with immunosuppression and some immunocompetent patients.[3] However, it is not known if these antiviral treatment guidelines are adhered to in the United Kingdom (UK). Antiviral therapy has been shown to limit the duration and severity of zoster and accelerates healing.[4]

Zoster patients can experience a number of complications, the most common of which is PHN (see below). Other complications include; cranial and peripheral nerve palsies, encephalitis, and myelitis and, for ophthalmic zoster, chronic eye conditions and loss of vision;[4] few data exist describing the frequency of these complications, however they are believed to be very rare. More recent research has also suggested that zoster may be associated with increased risk of stroke; ophthalmic zoster was associated with over three times the risk of stroke in the 6 months after zoster onset.[5,6]

1.1.1.2. Pathogenesis of zoster

Primary varicella-zoster virus (VZV) infection manifests itself as varicella (chickenpox) infection, which is a highly infectious disease usually occurring before the age of ten in temperate

climates, after which the VZV lies dormant in sensory ganglia for many decades.[4] Zoster arises from the reactivation of latent VZV in sensory nerve cells,[7] whereupon the virus spreads along the nerve to the dermatome (an area of skin supplied by a single spinal or cranial nerve).

Over fifty years ago Hope-Simpson proposed that immunity played a role in zoster reactivation.[8] VZV-specific T cell-mediated immunity is understood to prevent reactivation of latent VZV and plays a greater role in suppressing reactivation than humoral immunity.[9,10] The importance of cell-mediated immunity is supported by several lines of evidence, including: (1) the decline in VZV-specific cell-mediated immunity with age,[11,12] correlating with the increased frequency of zoster in older individuals. This contrasts to VZV-specific antibodies which remain relatively constant as people age;[13] (2) immunocompetent individuals having lower VZV-specific immunity at the start of their zoster episode, compared to non-zoster controls;[14-16] (3) patients with immunosuppressive conditions affecting cell-mediated immunity being at greater risk of zoster;[17,18] and finally, (4) that vaccination of adults with the live VZV vaccine reduces the incidence of zoster and PHN, suggesting that augmentation of the cellular immune response to VZV can reduce reactivation.[19]

Cell-mediated immunity involves mostly T cells recognising VZV-infected cells and bringing about their destruction. No small-animal model replicates the signs and symptoms of varicella and zoster, therefore understanding of zoster pathogenesis is limited.[9,12] VZV-specific CD8+ (or cytotoxic) T cells have been detected, which recognise VZV antigens and destroy the infected cell.[20] VZV-specific CD4+ (or helper) T cells, which recognize VZV antigens and release cytokines (predominantly interferon-γ[12]) to activate other immune responses, are also believed to play a role in suppressing VZV reactivation.[12,21]

1.1.1.3. Epidemiology and risk factors

In the pre-varicella vaccine era in North America, over 95% of adults (age>20 years) were seropositive for VZV[22], putting the majority of these populations at risk of zoster. The lifetime risk of zoster is around 25%, increasing to around 50% for those reaching 80 years of age.[23] The annual rate of zoster is around 3 to 4 cases per 1000 persons across all ages, and an estimated 88,650 zoster cases occur each year in the UK among immunocompetent individuals aged over 60.[24] These numbers are expected to increase as the population ages.

Waning cell-mediated immunity is understood to lead to viral reactivation; therefore increasing age, due to a general waning of cell-mediated immunity during life, and severe immunosuppression are well-established risk factors for zoster.[23] However, these risk factors

do not explain the vast majority of zoster cases; over half of all zoster cases occur in people under 64 years of age,[13,25] so zoster is not exclusively a disease affecting older individuals, and over 90% of zoster cases occur among immunocompetent patients.[26] Despite this, predictors of zoster beyond age and severe immunosuppression are not fully understood. A full review of risk factors for zoster can be found in chapter 2.

1.1.2. Postherpetic neuralgia

1.1.2.1. Clinical presentation, diagnosis and treatment

PHN is a neuropathic pain syndrome which can develop after an episode of zoster.[27] Definitions of PHN vary, though the most commonly used classification is persistent pain 90 days or longer following onset of zoster rash.[27] Diagnosis of PHN is made clinically, on the basis of a patient's history and a physical examination of sensory function. The pain experienced by patients with PHN is described as a burning or stabbing pain, and can be accompanied by allodynia (pain triggered by contact with non-painful stimuli). This pain can last for months, years, or until death.[27] The pain associated with PHN can thus have a significant effect upon a patient's quality of life, physical functioning and mental health.[28-30]

PHN is a challenging condition to treat and strategies focus on pain management rather than resolution.[27] There are currently no therapies which can modify the course of the condition. Medications shown in randomized trials to reduce pain associated with PHN include topical lidocaine, anticonvulsant agents, opioids, tricyclic antidepressants and capsaicin.[4] In clinical trials of available therapies, fewer than half of patients with PHN have a 50% or greater reduction in pain and adverse effects are common, particularly in older individuals.[27] Some evidence exists suggesting antivirals administered during the acute zoster episode may reduce the risk of PHN, however the findings are inconclusive.[31]

1.1.2.2. Pathogenesis of PHN

Acute zoster infection undoubtedly results in nerve damage to both the peripheral and central nervous system, yet the nature of the damage and the specific mechanism resulting in persistent pain are not fully understood.[32] There are two non-mutually exclusive hypotheses for the development of PHN; the first is that a persistence of the VZV following acute zoster, at higher levels than during latency, causes continued pain; and the second, after acute zoster infection there is increased neuronal excitability and an alteration of pain perception caused

by neural damage.[33,34] A recent study showed that greater VZV cell-mediated immune responses in the first week after zoster onset was associated with less zoster morbidity and lower frequency of PHN.[35] This finding suggests that among patients with a better cell-mediated immune response, virus replication is limited and the underlying cell-mediated immune response plays an important part in PHN susceptibility.

1.1.2.3. Epidemiology and risk factors of postherpetic neuralgia

PHN is the most frequent complication of zoster, and the most common neuropathic pain following infection, developing in approximately 12.5% of patients with zoster aged over 50 years.[23]

The evidence regarding determinants of PHN is particularly limited. Increasing age is a clear risk factor for PHN[4] and PHN is rarely seen among those below 50 years of age. Certain features of the acute zoster episode, such as rash severity and prodromal pain,[36,37] are also commonly cited risk factors, although the evidence has never been systematically reviewed. A detailed systematic review and meta-analysis of risk factors for PHN can be found in chapter 6.

1.1.3. Preventing zoster and postherpetic neuralgia through vaccination

The importance of zoster and PHN morbidity has led to large-scale vaccination programmes in the United States (US), the UK, Australia and elsewhere.[38] A live-attenuated vaccine, called *Zostavax*, is currently used which works by boosting pre-existing cell-mediated immunity. Initially licensed in 2006 for patients aged 60 years and over, it is now approved for use in those 50 years and over.[39] Due to concerns that the live vaccine may lead to a varicella-like or herpes zoster illness from the vaccine virus strain, the vaccine is contraindicated in patients with conditions, or undergoing therapy, associated with severe immunosuppression.[40,41]

The vaccine demonstrated an efficacy of approximately 51% for zoster and 67% for PHN in a randomised controlled trial,[19] later substantiated in vaccine effectiveness studies.[42,43] Efficacy declines in older age groups and with time since vaccination.[44]

Due to the high-cost of the zoster vaccine, its use is limited. In the UK it is available to patients aged 70, 78 and 79 years of age and as of December 2014 uptake was estimated at around 60%.[45] Uptake in the US, where individuals over 60 years are eligible, reached 27.9% in 2014,[46] having previously been very low;[42] low uptake has in part been attributed to the high-cost of

the vaccine and difficulties around patient reimbursement, as well as low public awareness and logistic issues relating to vaccine supply.

More recently a recombinant subunit vaccine (HZ/su) has been developed and shown in a large randomised placebo-controlled trial (n=15,411) among patients ≥50 years to have a vaccine efficacy of 97.2%.[47] The HZ/su vaccine was equally as effective in patients ≥70 years, as patients <70 years. As opposed to the live *Zostavax* vaccine, the HZ/su vaccine may also be suitable for patients with immunosuppression, because the risk of disease resulting from replication of the vaccine virus is prevented.

1.2. Aim, rationale and research questions

The overall aim of this research is to better understand risk factors for zoster and PHN to inform vaccination policy. Considerable research has been carried out demonstrating the effect of older age and severe immunosuppression on the risk of zoster, and to a lesser extent PHN, however evidence regarding other risk factors is limited. Given the high frequency of zoster which is set to increase in the ageing population, and the intractability and lack of effective treatments for PHN, identifying groups who would benefit from the effective zoster vaccine could have important public health benefits (assuming the vaccine is safe, effective and sufficiently durable in these patients groups).

Three observational studies using electronic health records (EHR) data were conducted to answer the following research questions.

1.2.1. What are the risk factors for herpes zoster?

The first study of this thesis investigates the effects of possible risk factors for zoster. Many previous studies investigating risk factors for zoster have suffered from low power. Furthermore, few studies have evaluated multiple risk factors simultaneously, which has not enabled a consistent methodological approach to be applied to various factors.

A population based matched case-control study was therefore conducted, using data from the Clinical Practice Research Datalink (CPRD) to assess risk factors for zoster, namely autoimmune conditions including rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), and inflammatory bowel disease (IBD), and other medical conditions such as diabetes mellitus, chronic obstructive pulmonary disorder (COPD), chronic kidney disease (CKD), asthma and depression. A case-control study was carried out as its design makes it convenient to look at multiple exposures.

1.2.2. Who receives antiviral therapy following diagnosis of herpes zoster?

The second study aims to analyse antiviral prescription patterns after a zoster diagnosis. As PHN risk may be modified by antiviral use, an understanding of how commonly antivirals are used within UK general practice is an important preliminary step, before assessing risk factors for PHN. Research on the proportion of zoster individuals prescribed antivirals is limited and previous studies have reported overall use, rather than use by specific risk groups.

Therefore a descriptive study among zoster patients was carried out to calculate the proportion of zoster cases receiving antivirals. A risk factor analysis was also conducted to assess associations between patient characteristics and antiviral use.

1.2.3. What are the risk factors for postherpetic neuralgia?

The final research question of the thesis is to identify risk factors for the most common complication of zoster, PHN. For this question, a systematic review of risk factors for PHN was carried out. Following the review, a cohort study was conducted among previously identified zoster patients to identify those at higher risk of developing PHN. A cohort study design was chosen as it allowed the estimation of the incidence of PHN following zoster. This approach also allowed inclusion of all zoster cases, thus maximising the power of the study and reducing the possibility of selection bias.

1.3. Outline of thesis

The thesis follows the research paper style format, with articles incorporated into the chapters. Five articles have been written, four of which are published and one accepted, in peer-reviewed journals. Each chapter containing a research article is opened with a concise introduction describing the structure of the chapter. The original formatting of the journal articles has been kept. In some chapters the paper is followed by additional analyses and discussion, which could not be included in the published or submitted paper, due to length restrictions. There is some repetition in the thesis, as the chapters were written as separate publications.

Below is an outline of the thesis, describing the content of each chapter:

Chapter 2 presents a published literature review of the epidemiology and prevention of zoster, with an in-depth discussion of risk factors for zoster.

Chapter 3 provides a detailed account of the general methods which are relevant to the three key research questions. Specifically, it initially describes the data sources utilised in the thesis. It goes on to outline how zoster and PHN were defined. Finally, it outlines the definitions of other explanatory variables in the thesis.

Chapter 4 incorporates the first research paper; a population-based case-control study of risk factors for zoster.

The second research paper, a description of who is getting treated with antivirals in UK primary care, after a zoster diagnosis, is presented in *chapter 5.*

Chapter 6 contains a systematic review and meta-analysis of risk factors for PHN.

Chapter 7 presents the study investigating risk factors for PHN, nested within zoster patients.

In *Chapter 8* the findings from the thesis are summarised and discussed in the context of what was previously known on this topic. The suitability of the data sources for answering the research questions are then discussed and the implications of the findings on future research and clinical practice are explored.

1.4. Chapter summary

Introduction

- Zoster is a common dermatological condition caused by the reactivation of VZV, during periods of suppressed T cell-mediated immunity. It is more common in older and immunosuppressed individuals.
- Zoster can cause a number of complications, the most common of which is PHN, a neuropathic pain which can last for months to years, and affects approximately 12.5% of zoster patients over 50 years of age. The pathogenesis and risk factors for PHN are poorly understood.
- Zoster, and thereby PHN, can now be prevented through vaccination. However, the vaccines high-cost means its use is limited to older individuals, and because it is a live vaccine, it cannot be administered to immunosuppressed individuals.
- This thesis aims to better understand risk factors for zoster and PHN.

Chapter 2: Epidemiology and prevention of herpes zoster: literature review

2.1. Introduction

This chapter provides a general overview of the epidemiology and prevention of zoster, with a particular focus on describing risk factors for zoster. Current Dermatology Reports invited a literature review on this topic, and it appears below. As the review was carried out in 2011, evidence on zoster risk factors published between 2011 and 2016 has been gathered, and is summarised after the paper.

The Epidemiology and Prevention of Herpes Zoster

Harriet J. Forbes · Sara L. Thomas · Sinéad M. Langan

Published online: 18 January 2012

Abstract Herpes zoster is a common disease among older individuals, affecting approximately 25% of people in their lifetime and resulting in appreciable morbidity. The risk of zoster increases sharply with age and immunosuppression, yet relatively little is known about other risk factors for zoster. A vaccine for zoster is now available that holds the potential to reduce incidence of zoster and its complications. In this review, the recent literature on zoster incidence and potential risk factors for the disease are summarized. Current methods of preventing zoster and its associated morbidity are discussed, including zoster vaccine and the use of antivirals.

Keywords Shingles · Herpes zoster · Epidemiology · Incidence · Vaccine

Introduction

Herpes zoster is a common disease among older individuals, with a lifetime risk of 10% to 30% that rises to 50% among those living to ≥85 years [1•]. It is caused by the reactivation of latent varicella zoster virus (VZV), which can lie dormant for many decades after varicella (chickenpox) infection. Reactivation is thought to result from waning cell-mediated immunity. Zoster typically presents as a painful unilateral vesicular dermatomal rash (Fig. 1) that causes acute morbidity lasting between 2 weeks and 1 month [2].

The most common complication of zoster is post-herpetic neuralgia (PHN), which develops in around 20% of individuals aged ≥50 years [3]. PHN is often defined as pain persisting for >90 days after the onset of the rash; the pain can be very severe and remain for years [4]. Although zoster is rarely fatal, the pain associated with the acute phase of the disease and subsequent PHN significantly reduces quality of life [5]. Other rarer complications of zoster, such as cranial and peripheral nerve palsies [6], encephalitis and myelitis [7], and stroke [8, 9], have been described but few data exist about the frequency and severity of these complications.

There are two main reasons to present an update of the epidemiology and prevention of zoster. Firstly, zoster predominantly affects older populations, and with an increasingly aging population, it is likely to become increasingly common. Secondly, a vaccine to prevent zoster has recently been introduced for adult immunocompetent individuals in the United States and Australia, so this is an exciting era for zoster epidemiology and warrants increased research focus.

In this review, we summarize the literature on zoster, using key articles and reviews up to 2003 with more detailed investigation of recent research. We cover incidence of zoster and risk factors for the disease. Current methods for preventing zoster and its associated morbidity are discussed, including antivirals and the recently developed vaccine. Important unanswered clinical questions identified during the review are listed in Table 1.

Epidemiology

Incidence

Incidence in General Population

A systematic review published in 2004 found the overall incidence of zoster among immunocompetent subjects ranged from 1.2 to 4.8 per 1000 people per year [1•]; recent

studies from the United States [10, 11] and France [12] have also reported disease incidences within this range. The incidence of zoster increases markedly with age, with estimated incidences of up to 14.2 per 1000 people per year in those aged ≥50 years in the United States [1•], the United Kingdom [3], Italy [13], and Germany [14].

Incidence Among Immunosuppressed

The incidence of zoster among people with a generalized loss of cell-mediated immunity either from immunosuppressive disorders, such as HIV and cancer, or from the use of immunosuppressive therapies is much higher than in the general population, with incidence rates ranging from 14.5 to 53.6 per 1000 person-years [15–20]. In a retrospective cohort study using the Veteran Affairs administrative databases in the United States, the rate of zoster following a solid organ transplant was estimated at 22 per 1000 person-years overall, with higher rates seen among African American patients (37.6 per 1000 person-years) and heart transplant patients (40 per 1000 person-years) [17].

The incidence of zoster among patients on biologic drugs is of interest due to the increased use of these drugs and their potential impact on cellular immunity. A retrospective cohort study in Israel among psoriasis patients found zoster incidence was higher among patients treated with biologics such as infliximab (19.1 per 1000-person-years) compared to patients not on systemic therapy (4.6 per 1000 person-years) [21], but the difference in incidence did not reach statistical significance. Data from registries of patients with rheumatic diseases treated with biological agents in Spain [22], Germany [23], and France [24] suggest an increased risk of zoster when these patients are treated with monoclonal antibody–tumor necrosis factor (TNF) inhibitors. However residual confounding may contribute to these findings. A longitudinal study from the United States of patients in the National Data Bank for Rheumatic Diseases found biologics were not a risk factor for zoster [25], whereas a retrospective cohort study using an American administrative data source of people with rheumatoid arthritis reported those taking biologic therapy were at higher risk of zoster (adjusted odds ratio [OR] 1.54; 95% CI, 1.04–2.29) compared to patients not taking disease-modifying drugs or corticosteroids (but those taking oral corticosteroids were at even higher risk (adjusted OR 2.51; 95 CI, 2.05–3.06)) [26]. Disentangling risk associated with disease severity and impact of therapy remain challenging.

Recurrent Incidence

It is widely believed that second episodes of zoster are very uncommon, except among immunosuppressed individuals for whom recurrent zoster is well described. Therefore, a surprising finding from a recent population-based, retrospective cohort study in Minnesota was that of 1530 individuals diagnosed with zoster and deemed "immunocompetent" at the time of diagnosis, a second zoster episode was recorded in 5.7% in the subsequent 8 years [27]. Misclassification of immune status is possible in this study: immune status was determined only at the time of the first zoster episode and individuals with HIV infection who had not yet developed AIDS-defining illnesses and those taking low doses of systemic corticosteroids (<5 mg/d) were deemed immunocompetent. Thus, the immunocompetent group may have included some individuals with moderate immunosuppression at baseline as well as some who became immunosuppressed during follow-up [27, 28]. In addition, a small proportion of the clinically diagnosed zoster cases could have had herpes simplex rather than zoster. Research using larger datasets and more detailed characterization of immune status over time would be useful to confirm these findings. As expected in

Table 1 Unanswered questions

What is the risk of zoster among older patients with specific co-morbidities?
Can newer antiviral agents, such as famciclovir and valacyclovir, reduce the duration and severity of post-herpetic neuralgia?
What is the absolute risk of zoster directly related to treatment with biologic medications?
What approach should clinicians take regarding interruption of therapy in patients receiving biologics to administer the live zoster vaccine?

the Minnesota study, risk of recurrent zoster was almost three times higher among the 139 immunosuppressed patients compared to those classified as immunocompetent (hazard ratio [HR] 2.80; 95% CI, 1.84–4.27).

Temporal Changes in Incidence

Despite an expectation that aging populations and increasing use of immunosuppressive therapies during the course of the 20th century could have caused an increase in occurrence of zoster, reports of temporal changes in zoster incidence are conflicting [1•]. Interest in trends in zoster incidence over time heightened after the introduction of the varicella vaccine because of concerns that by removing exogenous boosting of VZV immunity from varicella contacts [29], zoster incidence could rise among older unvaccinated individuals with latent VZV infection [30].

Varicella vaccine became available in the United States in 1995 for healthy children aged over 12 months, susceptible adolescents, and adults. Vaccine uptake in the United States was slow during the first 5 years but increased from 68% in 2000 to 89% in 2006 among 19- to 35- month-old children [31]. Studies of the impact of introduction of the varicella vaccine on zoster incidence have shown inconsistent findings. Jumaan et al. [32] report no increase in zoster incidence between 1993 and 2002 among patients enrolled with a health insurance organization in Washington state [32]. In contrast, two further US studies report increases in zoster incidence rates following varicella vaccination. A telephone survey in Massachusetts found an increase in zoster incidence from 2.77 to 5.25 cases per 1000 people between 1999 and 2003 [33]. A study using the Veterans Administration database reported that between 2000 and 2007 (when vaccine coverage was higher), zoster increased from 3.10 to 5.22 episodes per 1000 people aged ≥40 years, although rates per year were not standardized for age [34]. Interpretation of the impact of the vaccine on zoster also has to consider background trends in zoster incidence. A further US study described greater increases in zoster incidence rates before varicella vaccine licensure compared to post-licensure periods, although interpretation was complicated by exclusion of Medicare enrollees (ie, older individuals receiving Medicare health insurance) from the earlier estimate [31]. As most older individuals in the US are enrolled in Medicare and the majority of zoster episodes occur in this age group, the true incidence rates may be distorted. Increases in zoster incidence prior to varicella vaccine introduction have also been described in Canada [35], Australia [36], and Spain [37]. Whether population-based varicella vaccination affects zoster incidence remains controversial.

Risk Factors for Herpes Zoster

Any factor impacting on VZV-specific or general cell-mediated immunity may affect risk of zoster. However, beyond the two key risk factors of age and immunosuppression, relatively little is known. Potential risk factors for zoster are outlined below.

Factors Affecting General Cell-Mediated Immunity

Age

The most important risk factor for zoster is increasing age, with incidence rates rising among older individuals (see above). This is likely to be due to immunosenescence (the generalized waning of cell-mediated immunity over the life course), which puts individuals at greater risk of many infections [38], as well as waning of VZV-specific immunity with increasing time since primary infection.

Immunosuppression

As discussed in the section on zoster incidence, the incidence of zoster among patients with immunosuppressive diseases is far greater than among the general population. Patients with HIV have up to 10 times the risk of developing zoster compared to the general population [18], and in specific young African populations, the positive predictive value (PPV) for underlying HIV infection when zoster is present is 85% to 90% [39, 40]. The PPV will vary depending on HIV prevalence in the population; reported PPVs of zoster for HIV vary from 3.7% in Brazil to 91% in a Ugandan study population [41, 42]. The risk of zoster is also markedly increased among those with leukemia, lymphoma, and metastatic malignancies and among those with selected autoimmune disorders, although disentangling immunosuppression related to disease pathology from immunosuppressive therapies for these conditions (discussed below) is challenging [15, 26, 43–47]. Recent studies have indicated that diseases associated with less marked immune suppression may also increase the risk of zoster. A retrospective hospital-based cohort study in Japan showed an increased risk of zoster among diabetic patients (HR 2.38; 95% CI, 2.04–2.78) [48] as did a nested case–control study from Israel (OR 1.53; 95% CI, 1.44–1.62) [49]. Chronic obstructive pulmonary disorder (COPD) has also been associated with increased risk of zoster, again possibly reflecting the therapies used [50]. Although the magnitude of the risk is smaller than among patients with severe immunosuppression, the high prevalence of common diseases means that the absolute number of people affected may be significant.

Increased zoster incidence is also reported in specific high-risk groups with iatrogenic immunosuppression following treatment with cytotoxic drugs or therapies affecting the immune response. The increased risk of zoster identified among individuals with COPD or with autoimmune disorders such as rheumatoid arthritis, Wegener's granulomatosis, or systemic lupus erythematosus mentioned above may partly reflect use of corticosteroids or disease-modifying drugs. Recent observational data from a German and Spanish biologics registry has suggested additional increases in zoster incidence related to use of monoclonal drugs inhibiting TNF-α in rheumatoid arthritis treatment [22, 23], consistent with findings from randomized controlled trials and observational studies in large databases in the United Kingdom and United States. Findings from psoriasis biologic registries are awaited to identify the long-term effect of biologic therapies on zoster risk. Although the relative risk among people with major immunosuppression from specific diseases and/or therapeutic interventions is high, these individuals account for <10% of cases with zoster in most population-based studies [10, 51] from Europe and North America.

Gender

Thomas and Hall's [1•] systematic review suggested that female sex may be a risk factor for zoster. Subsequent studies from the United States, United Kingdom, Italy, France, and Germany have reported significantly higher incidence rates among women [3, 10, 12–14]. It is unclear to what extent the reported increased incidence rates in women reflect a bias due to differences in health-seeking behavior as opposed to biological mechanisms affecting cell-mediated immunity that could put women at higher risk [1•].

Diet, Smoking, and Alcohol Use

Diets low in micronutrients may increase zoster risk by diminishing cell-mediated immunity and hastening immunosenescence among older individuals. A UK case–control study found no association between intake of single micronutrients and risk of zoster; however, among individuals aged ≥60 years, combined low micronutrient intake and low vegetable intake were associated with increased risk of zoster, as was lower fruit intake (at all ages) [52]. These results suggested that a mixture of nutrients in the diet may be necessary to maintain immune system health. Accurate measurement of micronutrient and diet intake is notoriously difficult; however, the study found strong dose–response associations that give credence to the findings.

Smoking and alcohol can affect cell-mediated immunity [53, 54], although no studies have been specifically designed to look at their effect on zoster risk. A cohort study in North Carolina found smoking was associated with a markedly lower risk of zoster [55], whereas another study using routine data from UK general practices from 1991 to 92 found no association between smoking and zoster risk [1•].

Stress

Stress may increase risk of zoster as it affects a number of neuroendocrine functions that can affect cell-mediated immunity [56]. A case–control study in North Carolina found stressful life events were more common in zoster cases within the 6 months prior to rash onset than in age-matched controls (2.64 vs 1.82 events; P=0.008), although recall bias may have contributed to this finding [57]. Analyses of the same population using a cohort study design found some evidence that negatively perceived life events were weakly associated with risk of subsequent zoster (risk ratio [RR] 1.38; 95% CI, 0.96–1.97), although the study lacked power to detect a significant effect [55]. A retrospective cohort study in Taiwan found patients with a psychiatric illness were more likely to have an episode of zoster (HR 1.29; 95% CI, 1.18–1.38) [58], which may reflect increased stress among these patients.

Factors Affecting Varicella Zoster Virus-Specific Immunity

Age at Primary Infection

Individuals acquiring varicella later in life have been hypothesized to be at lower risk of zoster as their immunity to VZV may last to older ages. No published studies have looked at this hypothesis directly, but country of birth has been taken as a proxy for age at varicella infection. Typically, in temperate areas, varicella onset is during childhood, whereas onset is often delayed until adolescence or even adulthood in some tropical areas such as southern India, Sri Lanka, and the Caribbean. Late varicella acquisition has been suggested as the reason why people of black ethnicity in a US study of older individuals had around one third the risk of zoster compared with those of white ethnicity (OR 0.35; 95% CI, 0.24–0.51) [55].

There is also some evidence that very early acquisition of varicella, in utero or in early infancy, may increase the risk of zoster during childhood and adolescence, perhaps because the immune system is not able to establish VZV immunity at such a young age [59].

Varicella Contacts

Hope-Simpson [29] hypothesized in 1965 that exposure to individuals with varicella could naturally boost VZV-

specific immunity in individuals with latent VZV infection and thus could protect against zoster [29], leading to the concern, as outlined in the section on zoster incidence, that population-based varicella vaccination might lead to changes in the incidence of zoster. Hope-Simpson's theory has been supported by a UK population-based case–control study of incident zoster cases and age- and sex-matched controls. The study found increasing protection against zoster with increasing number of varicella contacts in the 10 years before zoster, and a similar association with child contacts (used as proxies for unrecognized varicella contacts) [1•]. In contrast, a recent US case–control study of individuals interviewed 2 months to 5 years after zoster diagnosis found no evidence that varicella contacts or child contacts protected against zoster [60]. Even participants with three or more varicella contacts over the past 10 years were not associated with a significantly increased* risk of zoster compared with participants with no contacts (OR 1.37; 95% CI, 0.82–2.27). However the incidence of varicella at the time of the US study was low in comparison to that in the UK study, due to the US population-based varicella vaccination program. Few participants in the US study had more than two contacts with varicella in the previous 10 years (2% of controls compared with 17% of controls in the UK study), and some of these contacts could have been mild cases of breakthrough varicella in vaccinated children. Thus, participants in the US study perhaps had insufficient exposure to varicella to provide exogenous boosting.

Other Risk Factors

Genetics

The possibility of genetic susceptibility to zoster and its associated morbidity has some support from genetic association studies. Zoster cases in Finland and Korea were more likely to carry certain polymorphisms of the interleukin-10 gene, an immunomodulatory cytokine that suppresses cell-mediated immunity, compared to healthy controls [61, 62]. A study in Japanese zoster patients also found an association between human leukocyte antigens (HLA) haplotypes and PHN cases [63]. Two case–control studies using family history of zoster as an indicator for genetic susceptibility to zoster found opposing results. Hicks et al. [64] reported finding a family history of zoster more commonly among incident zoster cases in the United States compared to controls with other skin diseases, whereas Gatti et al. [65] found no difference in family history of zoster between cases with PHN and controls without a history of zoster presenting with hypertension in Italy. Further research is needed to clarify whether there is inherited susceptibility to zoster or to PHN among those who develop zoster.

*error: should read decreased

Mechanical Trauma

Mechanical trauma has long been thought to be a risk factor for zoster, based largely on case reports. A case–control study published in 2004 found that mechanical trauma in the 6 months before rash onset was associated with an eightfold increased risk of zoster at the site of the trauma (OR 8.02; 95% CI, 2.24–28.69), and trauma within 1 month before rash onset was associated with a 12-fold increased risk (OR 12.07; 95% CI, 1.49–97.63) [66].

Immunotoxin Exposure

A cross-sectional study in the United States of people living close to a pesticide dump site found those living closer to the dump were more likely to report a history of zoster; however, the sequence between zoster events and residence near the dump was not ascertained [67].

Prevention

Vaccine

The zoster vaccine has been a significant breakthrough in this field. The live-attenuated VZV vaccine works by boosting pre-existing cell-mediated immunity, providing protection against zoster and PHN. It was initially shown to be efficacious in the Shingles Prevention Study (SPS), a US-based randomized, double-blind, placebo-controlled trial among 38,546 individuals aged 60 years and older, in which it reduced the incidence of zoster by 51% and PHN by 67% [68•]. Vaccine effectiveness was subsequently shown in a retrospective cohort study of 75,761 vaccinated individuals insured by the Kaiser Permanente health plan in California, with each matched to three unvaccinated controls; the incidence of zoster was reduced by 55% among individuals over 60 years of age [69•]. Using population-based data in Canada, the estimated number of 65-year-old individuals needed to vaccinate to prevent a case of zoster and a case of PHN is 11 (90% CI, 10–13) and 43 (90% CI, 33–53) [70].

The US Advisory Committee on Immunization Practices (ACIP) recommends routine vaccination among all persons over 60 years of age, excluding patients with major immunosuppression or those with an allergy to any vaccine components [71]. In the context of dermatology clinics, the vaccine should not be given to individuals receiving high-dose prednisolone and safety is unknown in relation to biologic drugs, for which the ACIP recommends vaccinating those in target age groups at least 1 month prior to commencement of treatment in the absence of contraindications. A US observational study assessing the use of zoster vaccination in older individuals with inflammatory and

autoimmune diseases identified 32 patients taking biologic drugs at the time of zoster vaccination; none developed zoster in the subsequent month [72]. Research using Medicare data from 2006 to 2009, currently available in abstract form only, report that among 387 biologic users there were no cases of zoster in the 6 weeks following zoster vaccine administration [73]. Further testing in a clinical trial is required before acceptable safety margins for the use of the live zoster vaccine in patients receiving biologics can be given or specific recommendations on safe intervals for temporary discontinuation of therapy prior to administration. The current literature does not provide clear answers regarding safety in individuals taking other immunosuppressants. The vaccine has also been introduced in Australia. Although the vaccine has not yet been introduced in the United Kingdom, the Joint Committee on Vaccinations and Immunisations (JCVI) has recommended that the zoster vaccine be introduced for immunocompetent individuals aged 70 to 79 years [74].

Vaccine side effects were assessed in 97% of the study participants in the SPS and the frequency of serious adverse events within 42 days of inoculation was the same in vaccinated (1.4%) and placebo groups (1.4%) [68•]. A further substudy of 6616 SPS participants (3345 vaccinated and 3271 placebo) gathered more detailed information on short-term events and hospitalizations over the entire follow-up period [75]. Local side effects at the inoculation site (eg, erythema, pain, swelling, rash, and pruritus) were more frequently reported in vaccinees (48%) than the unvaccinated group (16%), and having ≥1 inoculation-site adverse event was more common among those aged 60 to 69 years (56.6%) compared to individuals aged ≥70 years (39.2%). However, events were rarely long lasting or severe. Longer-term follow-up showed rates of hospitalization and death did not differ between the two groups [75].

Modelling work has suggested that zoster vaccine is cost-effective. Using data from the SPS and population-based data from Canada, Brisson et al. [76] suggested the most cost-effective strategy was vaccinating adults aged 65 to 75 years, with the main cost benefits being reduced PHN morbidity. One of the main challenges in calculating cost-effectiveness is uncertainty regarding duration of vaccine efficacy, due to the short duration of the SPS trial (mean follow-up of SPS was 3.4 years) [76]. The US Food and Drug Administration have also recently expanded the age range for the zoster vaccine to individuals aged 50 to 59 years on the basis of a large unpublished, multinational, randomized controlled trial showing efficacy of 70% in terms of reduction of incident zoster; further observational data of vaccine effectiveness are awaited from this age group, and previously discussed ACIP recommendations remain unchanged [77].

Despite the efficacy of the vaccine, its uptake in the US target population has been disappointing. Data from a US household survey from 2007 found 1.9% of adults aged 60 years and older were vaccinated against zoster, rising in 2008 to 6.7% [78]. In 2008, rates were lower among Hispanics (2.1%) and non-Hispanic blacks (2.5%) than non-Hispanic whites (7.6%). Both patient and provider barriers have been suggested as explanations for the low uptake of the zoster vaccine, such as the high vaccine cost, complex methods for reimbursement, and requirement for freezer storage [79, 80].

Vaccination coverage levels could be higher if the zoster vaccine was given at the same time as other vaccines. In December 2009, the US Food and Drug Administration stipulated that the zoster vaccine should not be given concurrently with the pneumococcal vaccine, after results from a randomized, double-blind, placebo-controlled trial by the manufacturer on 473 individuals aged ≥60 years found VZV antibody levels were lower among patients receiving concomitant zoster and pneumococcal vaccinations compared to those receiving the zoster vaccine 4 weeks after pneumococcal vaccine (VSV geometric mean titers ratio [concomitant/non-concomitant] 0.70; 95% CI, 0.61–0.80) [81]. A retrospective cohort study in a US state compared incidence rates of zoster, rather than antibody levels, over a 3-year period among individuals receiving both vaccines either concomitantly (n=7187) or with at least a 30-day gap (n=7179). The study found no difference in the incidence of zoster between the groups (HR 1.19; 95% CI, 0.81–1.74) [82]. The authors suggested that a thorough assessment be undertaken before introducing rules placing barriers on administration of the zoster vaccine, especially considering its low uptake.

Antivirals

Antivirals are used to limit pain of an acute zoster episode, and some evidence suggests they might also reduce the risk of developing PHN. A recent Cochrane review of five trials comparing acyclovir to placebo and one trial comparing famciclovir to placebo found little difference in prevalence of PHN 6 months after rash onset; however, the meta-analysis was limited to two of the acyclovir trials with the required data (summary RR 1.05; 95% CI, 0.87–1.27) [83]. This finding partly contrasted previous reviews in which different definitions of PHN were used. These meta-analyses found some evidence of an effect of acyclovir on reducing frequency of PHN [84]. A randomized controlled trial of 419 adults showed a significant reduction in median duration of PHN (although no reduction in PHN incidence) when famciclovir was given using a standard regime [85]. The authors of the Cochrane review suggested further trials be conducted on famciclovir and valacyclovir to clarify their role in reducing duration and

severity of PHN [83]. These newer agents are, however, significantly more expensive compared to acyclovir and are currently infrequently prescribed.

Antivirals may also be effective in protecting against incidence of zoster among severely immunosuppressed patient groups. For example, a double-blind, placebo-controlled trial of 77 patients undergoing allogenic hematopoietic cell transplant showed that 800 mg of acyclovir, given twice daily for 1 year after the procedure, significantly reduced the risk of zoster (HR 0.16; 95% CI, 0.04–0.74) [86]. With increasing numbers of people becoming immunosuppressed from modern therapies, antiviral use may be proven effective in reducing the incidence of zoster and its associated morbidity in certain high-risk groups.

Conclusions

The lifetime risk of zoster is high and has important consequences. The greatest breakthroughs in this field have arguably been the development of a highly effective, safe zoster vaccine that has the potential to significantly reduce incidence and morbidity of zoster and PHN, as well as a vaccine to prevent varicella, which could eventually lead to the appreciable reduction of the burden of zoster. Further research focusing on cost and logistics of the zoster vaccine needs attention due to its current low uptake in the United States. Despite the relatively high incidence of zoster in older individuals, relatively little is known about risk factors for zoster, and recent questions have been raised about risks associated with specific co-morbidities. Better understanding of the determinants of zoster could be an important step in preventing herpes zoster episodes and identifying target groups for the vaccine.

2.3. Risk factors for zoster: 2016 literature review update

Research exploring risk factors for zoster appearing after the publication of the above article, "The Epidemiology and Prevention of Herpes Zoster" (and herein referred to as the "2011 review"), are briefly summarised below. Table 2 below provides an overview of how literature published between 2011 and 2016 corroborates, challenges or extends the conclusions from the 2011 review.

Briefly, the 2016 literature review update has substantiated the findings from the 2011 review regarding older age[1,48] and severe immunosuppression[48-51] as major risk factors for zoster. The increased risk of zoster associated with female sex,[48,50-53] autoimmune conditions[49,54-60] and mechanical trauma[61,62] was similarly corroborated.

Since the 2011 review, the effects of anti- tumour necrosis factor (TNF) drugs, have been further investigated. Evidence from a systematic review suggests anti-TNF drugs increase the risk of zoster among RA patients by 60% (compared to conventional disease modifying anti-rheumatic drugs),[63] with some evidence that monoclonal antibody anti-TNFs pose greatest risk. However, in the review there was significant statistical heterogeneity between studies (I^2=80%) and one of the largest studies in the review concluded there was no evidence that new users of biologics were at greater risk of zoster, compared to new users of conventional DMARDs.[64] The effect of anti-TNF drugs among patients with psoriasis and IBD is similarly inconsistent.[58,64-66]

The 2011 review also suggested that more common medical conditions, associated with moderate immunosuppression, might increase the risk of zoster. The 2016 update found supporting evidence indicating that diabetes[48,50,52,67] and COPD[48,52] are associated with increased risks of zoster, of up to 45%. Additional research has suggested that other medical conditions may be risk factors for zoster including asthma,[48,51,68] CKD,[69-71] cancer,[48,51,72] cardiovascular disease[48,51,52] and peptic ulcer disease.[73] The risk of zoster was 5-80% greater for patients with these conditions, compared to the general population. However, a number of limitations were identified in these studies, including: 1) small study sizes; 2) inadequate adjustment for confounders; 3) lack of data on whether the associations were driven by the conditions themselves, or the use of immunosuppressive drugs; and 4) lack of data on how these risk factors varied by age. Therefore, the effect of these risk factors on zoster is not fully understood.

The 2016 update also identified two studies exploring recent negative life events as risk factors for zoster, in order to investigate the effects of stress. However, the effects of these life events were inconsistent between the studies.[74,75] This finding demonstrates that the very commonly cited risk factor for zoster, psychological stress, has yet to be comprehensively demonstrated as a risk factor in the epidemiological literature. The effect of varicella contact exposure,[1,76] age of primary varicella infection[48,51] and genetics[30,39] on zoster risk also remains unclear. Black ethnicity was substantiated as a protective factor against developing zoster, reducing the risk by 5 to 30%.[51,53,72]

Table 2: Overview of how literature published between 2011-2016 on zoster risk factors either corroborates, challenges or extends conclusions from the 2011 review

Exposure	Findings from main "2011 review"	2016 update: findings from papers published since 2011
Factors affecting general cell-mediated immunity		
Age	Increasing age is a risk factor for zoster with an estimated incidence of up to 14.2 per 1000 person years in those ≥50 years old in North America and Europe.	The effect of increasing age on risk of zoster was corroborated in a systematic review of zoster incidence studies, which confirmed a steep rise in zoster incidence after 50 years of age, with some suggestion that the incidence peaks around 75 years of age, whereupon it starts to plateau or decline.[1,48]
Gender	Female sex may be a risk factor for zoster.	Further studies support female sex as a risk factor for zoster; effect estimates ranged from 1.22 to 1.39.[48,50-53]
Severely immunosuppressive conditions/therapies	Zoster incidence in patients with severe immunosuppression is greater than in the general population; incidence rates range from 14.5 to 53.6 per 1000 person years.	Further research supports findings from the "2011 review".[48-51] The incidence of zoster in HIV patients is reducing, perhaps due to modern antiretroviral drugs; the rate of zoster among HIV patients using French hospital data reduced from 2955 per 100,000 person years in 1992-96 to 628 per 100,000 person years in 2009-2011.[17,77,78]
Autoimmune conditions	The risk of zoster is markedly increased among patients with autoimmune disorders, specifically RA, Wegener's granulomatosis, or SLE.	Further evidence supports the increased zoster risk in autoimmune conditions, compared to the general population, including RA (risk 2 fold greater),[57] IBD (risk 1.5 times greater),[58] SLE (risk 1.5 to 2.3 times greater),[49,59,60] primary Sjögren's syndrome,[54] bullous pemphigoid,[55] dermatomyositis and polymyositis.[56] Anti-TNF drugs appear to increase zoster risk among RA patients,[63] yet the effect in psoriasis[64-66] and IBD patients[58,64] is less clear.
COPD	One study suggested zoster risk was greater among patients with COPD, compared to the general population.	Two studies demonstrated an increased risk of zoster associated with COPD of around 20 to 30%.[48,52]
Diabetes	Two studies indicated diabetes was associated with increased risk of zoster, with effect estimates ranging from 1.53 to 2.38.	Four further studies found diabetes was associated with an increased risk of zoster, with effect estimates ranging from 1.04 to 1.45,[48,50,52,67] and a further study distinguished between diabetes type and reported only type 2 diabetes was associated with zoster.[79]

Table 2: (continued)

Exposure	Findings from main "2011 review"	2016 update: findings from papers published since 2011
Mental health problems	Negative life events and psychiatric disease were identified as risk factors for zoster in single studies.	Two studies assessed the effect of negative life events on zoster risk; one reported these events increased the risk of zoster,[74] whilst another found no evidence of increased risk.[75] Two case-control studies found depression was associated with an increased risk of zoster, ranging from 1.5-4 times the odds,[52,74] whilst an Australian cohort study found no association with depression or anxiety.[51]
Asthma	*No evidence in 2011 review.*	Three studies have reported an increased risk of zoster associated with asthma, with effect estimates ranging from 1.12 to 1.70.[48,51,68]
CKD	*No evidence in 2011 review.*	Recent studies indicate CKD is a risk factor for zoster,[69] associated with 20 to 60% increased risk, with greater risk among CKD patients on dialysis.[70,71] All studies used Taiwanese health records.
Factors affecting general cell-mediated immunity (continued)		
Cancer	*No evidence in 2011 review.*	Non-haematological cancers were associated with over 10% increased risk of zoster in two studies,[48,72] whilst an Australian cohort study assessed all cancers (excluding non-melanoma skin cancer) and found a 35% increased risk of zoster.[51]
Cardiovascular disease	*No evidence in 2011 review.*	Since the review, studies have indicated a small but significantly increased risk of zoster associated with coronary heart disease[48,51,52] (effect estimates range from 1.09 to 1.24).
Statins	*No evidence in 2011 review.*	Three studies reported a small but significantly increased risk of zoster with statin use, with effect estimates ranging from 1.13 to 1.28.[80-82]
Peptic ulcer disease	*No evidence in 2011 review.*	One cohort study identified peptic ulcer disease as a risk factor for zoster, with almost 80% increased risk of zoster.[73]
Liver disease	*No evidence in 2011 review.*	There is no evidence that patients with cirrhosis are at increased risk of zoster.[83]
Diet, body mass index (BMI) smoking and alcohol use	Diets low in micronutrients may increase zoster risk, smoking may be associated with lower risk of zoster and no studies have assessed alcohol use as a risk factor for zoster.	An Australian cohort study[51] found an 18% decreased risk of zoster in current compared to never smokers in line with previous research, along with a 6% increased risk of zoster among past smokers. This same cohort study found no association with alcohol use or BMI, and zoster.

Table 2: (continued)

Exposure	Findings from main "2011 review"	2016 update: findings from papers published since 2011
Factors affecting VZV-specific cell-mediated immunity		
Age at primary infection / ethnicity	Later age of primary varicella infection may reduce the risk of zoster, potentially explaining the reduced risk of zoster in patients of black ethnicity originating from countries where varicella is contracted later in life.	The reduced risk of zoster in patients of black ethnicity was corroborated, with protective effects ranging from 5 to 30%.[51,53,72] A Spanish study reported a lower incidence of zoster in foreign born participants with those born in sub-Saharan Africa at 60% reduced risk,[48] however in an Australian cohort study, participants born in countries where varicella onset is late were not at decreased risk of zoster in univariate analysis.[51]
Varicella contacts	Natural boosting of VZV-specific immunity through exposure to varicella contacts was partially supported by epidemiological evidence.	A systematic review assessing exposure to varicella contacts and zoster risk found mixed results,[76] whilst two systematic reviews concluded zoster incidence has not clearly increased following the introduction of the varicella vaccine.[1,76]
Other risk factors		
Genetics	Evidence regarding genetic susceptibility to zoster is scare and inconsistent.	Two studies reported greater risk of zoster for patients with family history of zoster,[74,84] however the effect of genetics on zoster susceptibility remains unclear.
Mechanical Trauma	A single case-control study found mechanical trauma six months pre-zoster was associated with eightfold increased risk of zoster, though the study may suffer from recall bias.	Two studies using routinely collected data reported physical trauma was associated with over three times the risk of zoster.[61,62] The effect appeared relatively immediate, specifically during the first week following trauma.
Physical limitation	*No evidence in 2011 review.*	An Australian cohort study reported that patients with a severe physical limitation were 30% more likely to develop zoster.[51]
Health-seeking behaviour	*No evidence in 2011 review.*	An Australian cohort study found patients attending cancer screening programmes and taking supplements were up to 17% more likely to develop zoster, and patients living in regional areas, rather than cities, were less likely to develop zoster.[51]

2.4. Chapter summary

Epidemiology and prevention of herpes zoster

- A review of the epidemiology and prevention of zoster was carried out in 2011, and evidence regarding zoster risk factors was updated in 2016.
- The lifetime risk of zoster is high and it can have significant consequences.
- The greatest breakthrough in this field has been the development of an effective, safe zoster vaccine, which has the potential to significantly reduce the incidence and morbidity of zoster and PHN.
- Well demonstrated risk factors for zoster include age, severe immunosuppression and mechanical trauma. Newer evidence indicates biologics may increase the risk zoster.
- Various common conditions, including diabetes, asthma, COPD, CKD, cardiovascular disease, cancer and peptic ulcer disease, have been indicated as zoster risk factors. However, a number of limitations were identified and the effect of these risk factors on zoster remains unclear.
- Better understanding of the determinants of zoster could be an important step in preventing zoster episodes and identifying target groups for the vaccine.

Chapter 3: Data sources and variable definitions

This chapter summarises the data sources utilised in this thesis and outlines how the main outcomes of interest (zoster and PHN) and the explanatory variables were defined.

3.1. Data sources

This study will utilise data from two EHR databases: the UK CPRD and the Hospital Episode Statistics (HES) database.

3.1.1. The Clinical Practice Research Datalink

3.1.1.1. Overview

CPRD is a large computerised database of anonymised patient records from UK primary care. At the time this research project was carried out, over 600 general practices contributed data from over 12 million patients and over 5 million currently registered patients. Approximately 7% of the UK population were represented, making it one of the largest sources of electronic primary care data in the world for research. Enrolled practices use a specific information technology (IT) system, called Vision, which uses coded and free text data to record information. Practices agree to participate, however individual patients may opt out upon request. Over 98% of the UK population are registered at a general practice and studies have shown that patients in CPRD are broadly representative of the UK population in terms of age, sex and ethnicity.[85]

The general practitioner (GP) in the UK acts as the gatekeeper of primary care and specialist referrals, therefore the majority of patients will seek care initially from their GP for health-related issues. This system results in a rich source of patient-level health data, including all consultations, diagnoses, prescriptions, tests, immunizations, referral to hospitals and hospitalizations. Unlike many administrative databases, particularly those collected for insurance purposes, CPRD also contains some lifestyle and anthropometric data, such as smoking behaviours and BMI.

3.1.1.2. Data structure and coding

CPRD release new database builds on a monthly basis. For this thesis the January 2012 build was used, except for the descriptive study of antiviral use (chapter 5) in which the June 2011 build was used. The data are split into several files and Table 1 below describes the main file types in CPRD used for this study, along with their contents. The patient-level files can be linked using a unique patient identifier, present in each file. The last three characters of this identifier also constitute a unique practice identifier, for linkage to the practice-level data.

Table 1: Description and contents of files types available and utilised in this thesis

File type	File contents
Patient	*Patient level demographic details including*; year of birth, gender, registration status (acceptable/unacceptable), death date, transfer out date.
Practice	*Practice level data including*; geographical region, 'Up to standard' date (date CPRD have classed the practice data sufficient quality for research), last data collection date (for the practice).
Consultation	*Patient level data on consultations with GP*; date of consultation, type of consultation and duration of consultation.
Clinical	*Patient level data on clinical events including*; date of clinical event, diagnosis given or symptom recorded.
Additional Clinical Details	Additional detail regarding clinical events, such as number of cigarettes smoked per day and test results. The file is split into entity type, which relates to a specific type of data. There are a total of 460 different entity types. For example, entity “type one” records information on blood pressure.
Referral	*Patient level data on referrals to specialist services including*; date of referral, diagnosis given, method of referral, referral specialty, urgency of referral.
Therapy	*Patient level data on drug prescriptions and apparatus including;* date of prescription, CPRD product code for the prescription.

GPs in the UK record medical and non-medical events using the hierarchical Read code classification system.[86] This system covers a range of areas including symptoms, diagnoses and administrative processes. The Read code hierarchy is organised into chapters and subchapters, with initial values representing high-level categories and following values specifying further detail on the event. Therapy prescriptions are recorded using the Multilex product dictionary, and include pharmaceuticals, drug appliances or devices. CPRD have translated these Read and Multilex codes into medical and product codes respectively, and created dictionaries that can be easily searched. For this thesis the dictionary versions 1.3.2 were used.

Defining follow-up for individual patients

Although records go back many years, CPRD recommend restricting the start of follow-up period to be the latest of practice 'up to standard' date or the date the patient first registered at the practice. They also recommend ending follow-up at the earliest of the following; when the patient died, transferred out of the practice, or when data were last collected on that practice.

3.1.1.3. Data Quality and Validity of Information

CPRD data undergoes some checks to ensure the data meet certain standards before release.[87] These checks occur at the practice and patient level. Practices are assessed and labelled 'up to standard' when the practice is considered to have continuous high quality data, fit for research. The practice must meet various criteria, such as a minimum referral rate per 100 patients. Patient level data are marked as "acceptable" for research, where certain criteria are met, such as: 1) age at end of follow-up is below 115 years; and 2) year of birth is recorded.

Guidance documents for practices contributing to CPRD ask GPs to record various aspects of a patients' medical details including; all significant clinical events from a patients history at registration and as they occur, indications for therapy prescriptions, all known hospitalisations and cause of death. However, data completeness may vary substantially over time, by population or type of data.

Recording of certain data types has been improved by the introduction of the Quality and Outcomes Framework (QoF), which encourages recording of key data items through an incentivised payment programme for GPs.[88] QoF was introduced in 2004 and sets out a series of data fields for collection, such as the BMI status of diabetes patients and the delivery of services to patients with severe mental health conditions. The completeness of data for factors included in QoF increased following the introduction of this programme.

Diagnostic validity in the CPRD is generally considered to be an advantage of the database. A systematic review of studies validating a variety of disease diagnoses found the median proportion of CPRD-defined cases with a confirmed diagnosis was 89%[89] (positive predictive value (PPV) of a recorded diagnosis). However, the PPVs ranged from 24 to 100% for individual diseases and the review acknowledged that validation studies were limited due to their size and frequently restricted to specific populations. Furthermore, the same systematic review noted that negative predictive values (NPV) are very rarely assessed in CPRD validation studies,

due to the financial implications of sampling a vast number of patients without the diagnostic codes of interest. The lack of information on the NPV is an acknowledged weakness of CPRD data.

3.1.2. Linked Hospital Episodes Statistics

3.1.2.1. Overview

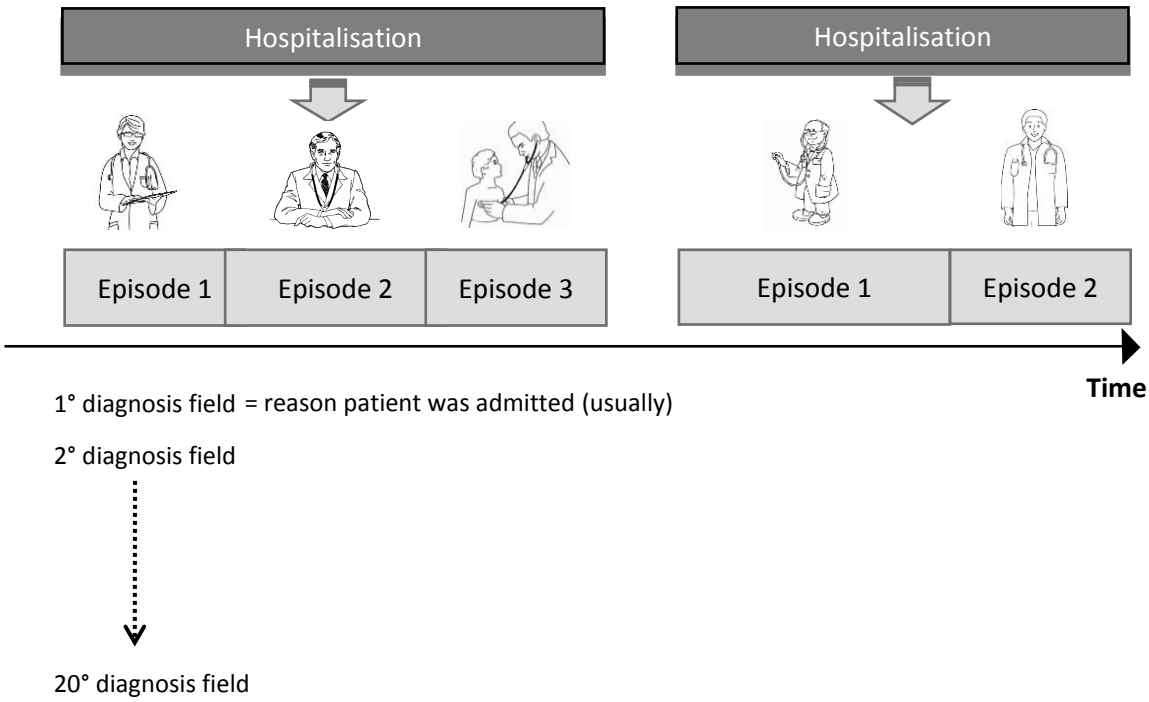
A subset of English CPRD practices participate in a linkage scheme, where related datasets are linked to CPRD. One of these datasets is HES, a secondary care database of hospital admissions from all National Health Service (NHS) trusts throughout England. Patients in CPRD are linked to HES data using deterministic matching (where all or some identifiers are required to match exactly) on a combination of the patient's NHS number, gender, and partial date of birth. The research in this thesis uses hospitalisation data from April 1997 to March 2012, during which time 375/497 (75%) of English practices participated in the linkage scheme. Linked HES data contains information on inpatient admissions only (limited outpatient data did not become available until September 2014). HES contains comprehensive diagnostic information, however prescription data are not currently available.

3.1.2.2. Data structure and coding

The structure of HES data are demonstrated in Figure 1 below. HES data are divided into "hospitalisations", which relate to a stay in hospital. For each hospitalisation there may be one to many "episodes", an episode being a time period for which a patient is under the care of a particular consultant. Within an episode, a patient has a primary diagnosis and up to 20 further secondary diagnoses; the primary diagnosis field usually relates to the reason the patient was admitted. The data are provided to researchers as files relating to hospitalisations or episodes.

Clinical diagnoses in HES data are coded using the International Classification of Disease, tenth revision (ICD-10) system, developed by the World Health Organisation (WHO). It is organised into chapters, themed on particular medical areas, covering diagnoses and procedures. ICD-10 codes are made up of 6 or 7 digits; the first three digits indicate the medical category, the next three give information on the location, severity or aetiology and the 7th digit is optional, depending on the chapter.

Figure 1: HES data structure



Note: "hospitalisations" relate to a stay in hospital and "episodes" relate to a time period for which a patient is under the care of a particular consultant.

3.1.2.3. Data quality

HES data are collected during a patient's hospital stay, and are processed to allow hospitals to be paid for the care they deliver. HES data are also designed to enable secondary use, that is use for non-clinical purposes, such as research. Trained clinical coders input ICD-10 codes from unstructured, hand-written clinical notes. Data input by clinical coders are then sent to a data warehouse. At pre-arranged time-points in a year, HES then extracts a copy of the data, and carry out validation and data cleaning. Each variable undergoes a set of cleaning rules, for example each patients date of birth must lie between 1/1/1885 and the last day of the period being processed, and where invalid codes appear, they are overwritten with the code for "Unknown".[90]

Errors and omissions within HES data are acknowledged to occur;[91,92] in 2013/14 an audit of 8,990 episodes of care from 50 NHS trusts compared case notes to clinical codes, and estimated the error rate of clinical codes in admitted patient care data at 10.8%.[93] The errors may be entirely incorrect codes, or codes lacking detail of the clinical event.[94] The main reasons for errors are thought to be incomplete paper records and the lack of involvement from front-line clinicians in the coding process.[91] The impact of this level of coding inaccuracy on epidemiological research is difficult to quantify and is likely to vary according to the hospital

specialty and the study question. Despite this, data quality is improving over time and is considered sufficiently robust for health research.[95,96]

3.2. Creating code lists

To identify patient characteristics in CPRD and HES, such as diagnoses or therapies, code lists are created. A code list refers to a list of all codes indicating the patient characteristic or drug of interest. Code lists can be merged with the raw data to identify all patients with the characteristic or all patients prescribed the drug.

For this project, a systematic approach was used when creating diagnosis and product code lists. The relevant dictionaries of codes were searched using a STATA do file, such that all decisions on inclusion and exclusion criteria were recorded and were easily replicated.

The approach to creating a diagnosis code list was as follows:

- *All possible codes* were identified by creating a set of search terms (synonyms of the medical event) and looking for these in the entire Read or ICD-10 dictionary, within the Read term data field or ICD-10 Terms field. The Read code or ICD-10 hierarchy was additionally utilised to identify all codes within relevant chapters or sub-chapters. Codes not meeting the search criteria were dropped.
- *Final diagnosis codes* were selected by reviewing the possible codes with a clinician (in the majority of cases Dr Sinéad Langan, dermatologist) and collating a list of exclusion terms, which were then applied. Remaining codes were then compared to any available pre-existing code lists (for example if a code list for the medical condition had been created for a previous study) and discrepancies were assessed.

The approach to creating a product code list was as follows:

- *All possible codes* were identified by creating a set of search terms and looking for them within the entire product code dictionary, within the following data fields: product name, British National Formulary (BNF) header, drug substance and route of administration. Most codes were identified from the product name search, however if this data field was missing, searching the other data fields picked up extra terms. The hierarchical structure of the BNF dictionary was utilised by searching for codes within BNF chapters (using the BNF code data field). Product codes not meeting the search criteria were dropped.
- *Final therapy codes* were selected by reviewing the possible codes with a clinician (in the majority of cases Dr Sinéad Langan, dermatologist) and compiling a list of exclusion

terms, which were then applied. Remaining codes were compared to existing code lists where possible and discrepancies assessed.

All medical and product code lists can be found in appendix V.

3.3. Outcome definitions

3.3.1. Definition of zoster in CPRD and HES

Zoster diagnoses were identified in CPRD by Read codes in the clinical and referral files and in HES data by ICD-10 codes (listed in appendix V).

Patients were required to be ≥18 years of age at zoster diagnosis, as zoster among children is very rare. The zoster diagnosis had to occur within the patient's follow-up period (see section 3.1.1.3). It was also necessary to identify patients with a first ever episode of zoster, as recurrent zoster is rare and its aetiology and clinical course is believed to be different to the majority of zoster episodes.

It was important for the thesis' objectives to identify incident rather than prevalent cases of zoster, to ensure the optimal accuracy of diagnosis date. In order to ensure this, patients were required to have 12 months registration in CPRD without a zoster diagnosis. This 12-month threshold is in line with research by Lewis et al,[97] which reported that in routinely collected data, recording of prevalent cases is more likely shortly after registration at a general practice, therefore it is common practice not to include diagnoses recorded shortly after registration.

Incident zoster cases in HES data were identified by ICD-10 codes (B02, B02.0, B02.1, B02.31, B02.7, B02.8, B02.9, G53.0). Although the majority of zoster cases do not require in-patient care, a small proportion of cases require hospitalisation.[26] Identifying hospitalisations due to zoster is challenging, as it is not easy to determine whether zoster triggered the admission, occurred during hospitalisation or was associated with admission for another reason. HES data contain up to 20 diagnoses per episode, however hospitalisations were only considered to be related to zoster if the zoster diagnosis was recorded in the primary field of any episode during a hospitalisation (see Figure 1: HES data structure). This is because it is not possible to identify whether records in any of the secondary fields are incident zoster, history of zoster or misdiagnosis of zoster. For zoster cases identified in HES the date of hospital admission was taken as zoster date.

If zoster was identified in both HES data and CPRD, the earliest recorded zoster diagnosis was used.

3.3.2. Postherpetic neuralgia

This section describes some of the challenges of defining PHN in EHR data, as well as a summary of how researchers have identified PHN in previous studies. The method used to identify PHN patients in CPRD is then outlined in greater detail.

Background information on the management of PHN in UK primary care

The UK Clinical Knowledge Summary on the management of PHN (last revised February 2014)[98] suggests patients with zoster-associated pain are treated as follows: initially, with paracetamol in combination with codeine if necessary; where this proves ineffective, tricyclic antidepressants or anticonvulsants are recommended for 4-6 weeks. Clinicians are also encouraged to consider using capsaicin cream 0.075% and lidocaine 5% medicated plasters on the affected areas to relieve pain. For patients awaiting referral to pain specialists, if the above treatments have failed, GPs are recommended to consider prescribing a short course of tramadol. The chosen treatment depends on patient characteristics (such as their age, comorbidity and frailty), the phase of the illness (acute or established PHN), local prescribing preferences and physician preferences. The pharmacological management of PHN patients may therefore be heterogeneous.

Challenges in defining PHN using EHR data:

There are two main avenues for identifying PHN from CPRD records namely (1) looking for clinical records indicating a PHN diagnosis or continuous post-zoster pain that would meet the criteria for PHN, and (2) looking for prescriptions for treatments that are given for PHN.

Long-term pain due to PHN is difficult to capture in EHR databases such as CPRD, for a variety of reasons:

- *There is no single definition of PHN.* The definition of PHN varies in the literature, primarily in terms of when zoster-associated pain becomes classified as PHN. The most accepted definition of PHN is pain persisting beyond 90 days of rash onset, however some GPs and researchers may diagnose PHN 30 days following zoster.

- *PHN treatments have various clinical indications, therefore prescriptions for PHN medications may not be sufficient to confirm PHN.* PHN drug treatments such as codeine or anticonvulsants are not exclusively given for PHN. As clinicians in the UK are not required to record the indication for every prescription, it cannot be confirmed whether a prescription was given for PHN.
- *PHN pain codes are not always specific.* The pain codes available and used by some GPs to diagnose PHN are often non-specific (such as "neuralgia" or "neuropathic pain"), so again it is difficult to be certain the pain is due to PHN.
- *Patients may be referred to secondary care for pain management*. The UK Clinical Knowledge Summaries suggest that if pain is not controlled, despite medical advice and trials of two drug treatments (normally about 8–12 weeks [56-84 days] after starting treatment), or adverse effects limit treatment, doctors should consider referral to a pain clinic or seek specialist advice.[98] Therefore some PHN patients may be missed in CPRD if treatment is provided in secondary care. However, these patients would typically be referred back to primary care for ongoing treatment.
- *Patients may not attend primary care for pain-management.* Patients may not seek care from their GP for a number of reasons: (i) they may establish stable pain regimens before 90 days that no longer require repeated physician visits (many painkillers used in PHN pain management can be obtained over-the-counter); (ii) they may seek second opinions and alternative therapies outside the primary practice; (iii) they may resign themselves to pain as PHN is often refractory to treatment; (iv) or they may develop new health concerns that displace PHN pain as the focus of their visits. The implications of the above factors are that there is likely to be decreasing sensitivity of capturing PHN in EHR data with increasing time since zoster.

How researchers currently deal with PHN in EHR data

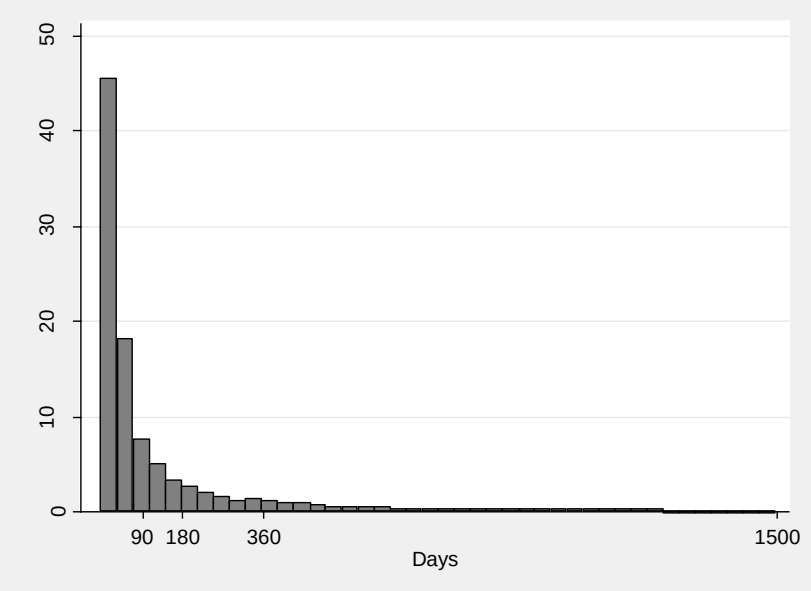
Researchers have used a variety of techniques to ascertain PHN patients in EHR data (see Table 2 below for some examples). Most researchers use evidence within a certain time-frame following zoster to define their PHN cases. The presence of PHN diagnosis codes (if available) and/or zoster plus neuropathic pain codes are widely used. Hall et al identified patients with a PHN code (without a requirement for previous zoster) or a code for neuropathy or neuropathic pain 3 to 6 months following an acute zoster code in CPRD. They validated their definition in a sample of 108 patients with PHN diagnosed between 2006 and 2010.[99] Questionnaires were sent to GPs to confirm PHN. The response rate was 86.8% and the PPV for PHN was 91%. This finding appears to suggest using PHN codes and zoster with a later nerve pain code is effective at identifying PHN patients in CPRD. However, this algorithm may not be reliable; it could be

argued that in CPRD, the majority of PHN codes may not indicate PHN itself, but zoster-associated pain shortly after zoster. Figure 2 below shows the distribution of time from zoster diagnosis to PHN code in patients with a first ever zoster code in CPRD. This figure suggests almost 70% of the codes occur within 90 days of zoster; as the most accepted definition of PHN is pain after 90 days, none of these codes alone would meet the criteria for PHN.

Table 2: Some examples of PHN definitions in previous studies using EHR data

First author, year	Database, country	Definition of PHN	Exclusions
Opstelten, 2002[13]	Primary care records, Netherlands	Any evidence of pain or analgesic prescription in patients' medical record 1 and 3 months following zoster	None
Gauthier, 2009[100]	CPRD, UK	Diagnostic code for PHN; *or* Neuropathic pain medication (topical analgesics, tricyclic antidepressants, anticonvulsants and tramadol) >1 to >12 months and >3 to <12 months post-zoster diagnosis. Assessed PHN severity from prescribed medications.	Diabetic neuropathy, epilepsy, recurrent zoster
Gialloreti, 2010[101]	Primary-care database and national hospital-discharge records covering four major regions in Italy 2003-05.	ICD9-CM code for zoster and a prescription for any drug commonly prescribed for PHN (tramadol, anti-epileptics, tricyclic antidepressants capsaicin cream or lidocaine) 3-12 months and 1-12 months after zoster diagnosis; *or* ICD9-CM code for PHN within the same time-frame	Immunosuppressed patients
Hall, 2013[99]	CPRD, UK	PHN code; *or* Code for neuropathy or neuropathic pain code 3-6 months following acute zoster code	None
Langan, 2013[42]	Medicare, USA	Zoster code 90 days following incident zoster, with a prescription of analgesia, anticonvulsant, antidepressant on the same day; *or* Non-specific neuralgia/neurological complications code 90 days following incident zoster.	None

Figure 2: Distribution of time from zoster diagnosis to PHN code appearing, in CPRD patients with first ever zoster



Some researchers have additionally used medications prescribed within a time frame following zoster to identify PHN cases. The use of relevant medications following zoster to identify PHN has not been validated in CPRD, however a US study by Klompas *et al*, developed an algorithm to identify PHN patients using administrative data, incorporating medication history into their final definition.[102] They used the Harvard Vanguard Medical Associates database, an ambulatory practice group that provides primary and specialty care to more than 550,000 patients in eastern Massachusetts. This database uses ICD version 9 (ICD-9), which has no code for PHN. Patients included were aged 20 years or older, with an ICD-9 code for zoster, in the calendar year 2008.

Klompas et al focused on identifying persistent pain 30 days following zoster and developed an algorithm with a sensitivity of 86% and PPV of 78%. In the algorithm, they required two or more visits with an ICD-9 code for zoster 21 days or more apart *and* a new prescription for an analgesic, antidepressant or anticonvulsant; *or* an ICD-9 code for zoster with nervous system complications; *or* an ICD-9 for neuralgia within 180 days of a visit for zoster. This validation study was carried out in an administrative data source, which differs from CPRD in so far as rule out codes are more commonly used and certain diagnoses may be under-reported if there are no financial incentives to record them. However, some high-level elements of this algorithm were used to help identify patients with PHN in CPRD; specifically, using a combination of diagnostic and "new" prescription codes within specified time periods following acute zoster diagnosis.

Strategy to identify PHN patients in CPRD

Methods previously used to define PHN were considered and an approach was developed to identify patients with PHN in the study. The approach was motivated by the specific study objective; that is to identify risk factors for PHN. A definition which prioritised high specificity (correctly identifying those without the disease) rather than high sensitivity (correctly identifying those with the disease) was required to reduce the chance of type I error (incorrect rejection of a true null hypothesis);[103] in other words, reporting spurious associations by rejecting the null hypothesis when it is actually true.

Underlying definition of PHN

The underlying definition of PHN on which the algorithm was based was *pain persisting for at least 90 days following zoster*. Patients were assumed to have PHN at 90 days following zoster, even where evidence of PHN was, say, 180 days after zoster.

Exclusions

As anticonvulsant prescriptions were to form part of the PHN algorithm (described in detail below), patients with other indications for anticonvulsants (e.g. epilepsy) recorded pre-zoster were excluded. Also excluded were patients without 365 days follow-up after zoster diagnosis; as the definition would use data within 365 days from zoster diagnosis, it would not be possible to know whether individuals censored before 365 days without PHN met the PHN definition.

Identifying zoster patients with and without PHN

The case definition of PHN was categorised into three groups; diagnosed, probable and possible.

- *Diagnosed PHN*: a PHN code 90-365 days following zoster within either; a) the clinical or referral files in CPRD or b) a primary diagnosis field within any episode of HES for linked patients.
- *Probable PHN*: a first ever non-specific neuralgia code 90-365 days following zoster in CPRD; *or* an additional zoster code 90-365 days following zoster with a drug prescription for an anticonvulsant, tricyclic antidepressant, capsaicin cream or lidocaine patch (see Table 3 below for drug descriptions) *on the same day* in CPRD.

Due to an unrealistically low number of PHN cases being ascertained using the above criteria (n=3110/119,413; 2.6% of zoster patients) drug prescription data were utilized further. As GPs

in UK primary care are not required to record the indication for every prescription, it is plausible patients are prescribed medications for PHN, without the diagnosis being recorded. The PHN medications searched for and their indications are described in Table 3. To increase the likelihood of the medication being prescribed for PHN, "new" prescriptions were searched for, defined as no previous prescriptions of the same medication type 12 months to two weeks prior to zoster (medications may have been prescribed for pain management two weeks prior to zoster, if zoster initially presented without a rash- "*zoster sine herpete*").

Table 3. Medications used to treat PHN

Medication type	Specific drugs	Indications[1]
Mild Painkillers	*Paracetamol*	*Mild to moderate pain*
	Ibuprofen	
	Aspirin	
Strong painkillers	*Codeine*	*Mild to moderate pain, diarrhoea, cough suppression.*
	Dihydrocodeine	
	Dextropropoxyphene	
	Tramadol tablets or injection	*Moderate to severe pain*
Tricyclic antidepressants	*Amitriptyline*	*Depressive illness, neuropathic pain, chronic pain and migraine prophylaxis*
	Nortriptyline	
	Imipramine	
	Desipramine	
	Duloxetine	
Anticonvulsants	*Pregabalin*	*Seizures, peripheral neuropathic pain and migraine prophylaxis*
	Gabapentin	
	Valproate	
	Oxcarbazepine	
	Carbamazepine	
	Phenytoin	
	Lamotrigine	
Other	*Lidocaine patches*	*No other indications*
	Capsaicin cream 0.075%	*No other indications*

[1]According to BNF 2014

Note on selection of medications: Mild painkillers included paracetamol as indicated for PHN in the Clinical Knowledge Summaries, and other commonly used painkillers ibuprofen and aspirin were additionally included. Stronger painkillers included codeine and tramadol, as indicated in the Clinical Knowledge Summaries, as well as dihydrocodeine and dextropropoxyphene which are indicated for treatment of neuropathic pain in the UK. Although other painkillers such as morphine and oxycodone can be used for neuropathic pain treatment, their use is not recommended for treating neuropathic pain in primary care[98]. Amitriptyline is clinically the most widely used tricyclic antidepressant for treatment of PHN yet nortriptyline, protriptyline, imipramine, desipramine were also included as they are occasionally used. Pregabalin and gabapentin are the most commonly used anticonvulsants in PHN treatment, yet others also indicated for PHN were included. Finally capsaicin cream 0.075% and lidocaine patch 5% were included, given specifically for PHN.

Medications appearing 90-180 days (rather than 90-365 days) were considered to further reduce misclassification of PHN. To get a sense of whether a PHN-medication was likely to have been given for PHN, or another condition, the *expected* number of "new" PHN-related prescriptions in similar patients without recent zoster was estimated. This was achieved by comparing the prescription patterns among the study cohort with age, sex and practice matched patients without zoster (using controls from the case-control study described in

Chapter 4 assessing risk factors for zoster). After applying the same exclusion criteria to the non-zoster controls as with the zoster cases (at least 365 days follow-up from their index date, no neuropathic pain syndromes or epilepsy prior to index date) and randomly selecting 1 control per zoster patient (see Table 4).

Table 4: Proportion of patients within the zoster cohort, and a similar non-zoster population, receiving a "new" PHN medication 90-180 days following zoster diagnosis

PHN medication	% of zoster study cohort (N= 117,815)	% of similar non-zoster sample (N= 117,815)
Anticonvulsants	1.65	0.25
Tricyclic antidepressants	2.84	0.69
Lidocaine patches	0.09	0.01
Capsaicin cream	0.25	<0.01
Strong painkillers	4.42	2.98
Mild Painkillers	2.51	2.05

Note: 1,598 patients from the study cohort had no matched control after exclusion criteria were applied

Table 4 demonstrates that "new" anticonvulsants, antidepressants, lidocaine patches and capsaicin creams were much more common among the zoster cohort than amongst controls. Patients with zoster had a slightly higher use of strong painkillers. On the basis of this evidence strong painkillers were not included in the definition of probable PHN, but instead possible PHN. Due to the comparable use of mild painkillers within the zoster and non-zoster samples, these medications were not used to identify further PHN patients. On browsing the clinical and therapeutic records of a selection of patients, two further criteria were added:

- *Further probable PHN*; patients with a "new" PHN drug prescription for an anticonvulsant, capsaicin cream or lidocaine patch 90-180 days following zoster; patients with a "new" tricyclic antidepressant 90-180 days following zoster with two additional criteria (to reduce misclassification of PHN, particularly with depression): firstly, no clinical diagnoses suggesting non-PHN indications on the same day as the tricyclic prescription [that is, any Read codes suggesting depressive diagnosis (symptoms of depression, such as "Crying all the time" or life-events with the potential to precipitate depression, such as divorce), a pain that may be chronic, or a need for migraine prophylaxis], as well as additional evidence of the drug being prescribed for zoster or PHN previously (in other words, a tricyclic antidepressant prescription 0-89 days following zoster, with a zoster/PHN code on the same day).

To capture other "possible" PHN patients, these criteria were added;

- *Possible PHN*: patients with a "new" tricyclic antidepressant prescription 90-180 days following zoster with no clinical diagnoses suggesting non-PHN indications on the same day as the tricyclic prescription (without additional evidence of the drug being prescribed for zoster or PHN 0-89 days after zoster); patients with a "new" strong painkiller 90-180 days following zoster with no clinical diagnoses suggesting non-PHN indications on the same day as the strong painkiller prescription (that is, any Read codes suggesting the presence of pain, diarrhoea, or cough) as well as additional evidence of the drug being prescribed for zoster or PHN previously (a strong pain killer prescription 0-89 days following zoster, with a zoster/PHN code on the same day); or patients with a neuropathic pain code 90-365 days following zoster.

The use of pain and symptom codes to diagnose PHN (e.g. "Chest pain", "Burning pain" or "Has tingling sensation") as well as referrals to pain clinics/specialists was considered; however their lack of specificity may have led to a number of false positive PHN cases. Finally, utilising information on the dosage of tricyclic antidepressant prescriptions was explored; when these drugs are given for neuropathic pain, patients are started on a low dose and graduated to a higher dose (compared to their use in patients with depression, who are more typically started on a high dose). Unfortunately the dosage information in the CPRD doesn't sufficiently capture information on graduated dose; therefore it was not possible to incorporate this into the definition.

The PHN definition, utilised in chapter 7, is summarised in Table 5 below.

Table 5: PHN definition used in this thesis

PHN classification	
Diagnosed PHN	PHN code* (90-365 days post-zoster)
Probable PHN	Zoster code and prescription consistent with PHN• on same day (90-365 days post-zoster)
	Non-specific neuralgia code (90-365 days post-zoster)
	NEW anticonvulsant or capsaicin cream or lidocaine patch prescription (90-180 days post-zoster)
	NEW tricyclic antidepressants 90-180 days post-zoster with no other indication on the day of the prescription, plus evidence of the drug being prescribed for zoster or PHN previously†
Possible PHN	**NEW** tricyclic antidepressants 90-180 days post-zoster with no other indication on the day of the prescription
	NEW strong painkiller 90-180 days following zoster with no other indication on the day of the prescription, plus evidence of the drug being prescribed for zoster or PHN previously†
	Non-specific neuropathic pain code (90-365 days post-zoster)

PHN: Postherpetic neuralgia.*Read code for PHN in CPRD or (for those with linked data) an ICD10 PHN code in the primary diagnosis field within any episode of linked HES. •Prescriptions included anticonvulsants, tricyclic antidepressants, capsaicin cream or lidocaine patch.
NEW prescriptions were defined as no previous prescriptions of the same medication type 12 months to two weeks prior to zoster, to increase the likelihood of the medication being prescribed for PHN (medications may have been prescribed for pain management two weeks pre-zoster, if zoster initially presented without a rash). †Here, previously is defined as a prescription 0-89 days following zoster.
Medications indicative of zoster were only considered in the 90-180 day period after zoster diagnosis (rather than 90-365 days) to reduce the chance of misclassifying other reasons for medication use as PHN.

3.4. Potential explanatory variables

Various other potential explanatory variables were defined for this thesis, including severe immunosuppressive conditions, autoimmune conditions, other comorbidities, demographic characteristics, lifestyle data and finally characteristics of the zoster episode. Below are detailed notes on how these variables were identified in CPRD records. HES data were not utilised to identify the medical conditions, as they are chronic, rather than acute conditions, and were thus assumed to be recorded in primary care records. All code lists are given in appendix V.

3.4.1. Severely immunosuppressive conditions

Severely immunosuppressive conditions were determined by the zoster vaccine contraindications set out by the Advisory Committee on Immunization Practices (ACIP), a group of medical and public health experts that develop recommendations on how to use vaccines in the US.[104] As the currently available zoster vaccine is a live vaccine, patients with primary or acquired immunodeficiency are assumed to be at risk of developing a varicella-like or zoster illness from the vaccine virus strain, if vaccinated. Therefore the contraindications

provide a list of conditions considered to result in severe immunosuppression. These contraindications are very similar to those set out in the UK's counterpart vaccine guidelines, the Green Book.[41]

The definition of severely immunosuppressive conditions used throughout this thesis therefore included a recent history (less than two years before the zoster diagnosis) of leukaemia or lymphoma, or any history of HIV, hematopoietic stem cell transplantation, myeloma or 'other unspecified cellular immune deficiencies' (e.g. pancytopenia). These diagnoses were all identified through the presence of Read codes in CPRDs clinical and referral files.

3.4.2. Immunosuppressive therapies

3.4.2.1. Corticosteroids

Definition

Two definitions of oral corticosteroid exposure were used: 1) a high-dose (≥20 milligrams (mg)/day), 14-day or longer course, in the month prior to zoster diagnosis (in keeping with the ACIP guidelines for zoster vaccine contraindications[104]); and 2) any dose of oral corticosteroids in three months prior to zoster diagnosis.

To identify high-dose prescriptions of 14 days or more in CPRD required some data cleaning. Below is some background information on how prescription data are collected in CPRD, how these data were cleaned, how prescription duration and prescription dose were calculated and finally, how missing data were handled.

Background on prescription data in CPRD

CPRD does not provide researchers with duration and dose for individual prescriptions. Instead, these must be generated using information from other variables.

Prescribing GPs select the drug, enter information on the prescription and can also enter free text. The drug name itself contains the dose in milligrams per tablet and the GP enters the total number of tablets to be prescribed, within in a field called *quantity*. The free text field contains the actual prescribing information; in other words how many tablets the patient should take each day, known as the *numeric daily dose*. Examples include, "take one daily" and "take one twice a day". To utilize this information, CPRD developed an algorithm to derive numeric daily dose from the free text and provide this to researchers.[105]

Data cleaning on oral corticosteroid prescriptions

A series of data-checking and data-cleaning tasks were carried out on oral corticosteroid prescriptions, including;

- Checking commonly occurring free texts; 500 of the most commonly used free texts were compared to the numeric daily dose for accuracy and 150 of the most commonly occurring free texts where numeric daily dose equalled zero were checked for accuracy. This approach captured over 90% of all prescriptions. Very few errors were found when checking the most commonly used free text against the numeric daily dose.
- The clinical and referral records for 20 randomly selected patients were browsed to verify that the duration and dose of the prescriptions were consistent with the diagnoses. For a single patient, consistency checks took on average 30 minutes, and 20 patients records were selected for review. This analysis demonstrated that patients prescribed short-term high-dose courses of oral corticosteroids tended to have codes consistent with an acute illness, such as an exacerbation of COPD or asthma. Longer term, lower doses were less easy to assign a reason for use.
- Tapering dose; the possibility of identifying tapering doses of oral corticosteroid prescriptions was explored by searching for words in the free text implying tapering doses, specifically, "*reduc*", *then*, *3*2*1*, *stop*. In total, 36 phrases were identified. However very few records had information about the actual reducing dose, therefore it was concluded that tapering doses could not be accurately identified.
- Unlikely values for quantity and numeric daily dose were excluded; for oral corticosteroids, individual prescription quantities of >1000 tablets and numeric daily dose's >40 were changed to missing.

Dealing with missing data

Although 99% of oral corticosteroid prescriptions had the quantity of tablets, as well as the dose of the tablets, data on numeric daily dose (required to calculate daily dose and duration of prescription) was missing for more than 30% of oral corticosteroid prescriptions. Steps were therefore taken to impute missing data for numeric daily dose.

Where numeric daily dose was missing for oral corticosteroids, the majority of the texts were "as directed". This suggests the dose may be uncommon. Alternatively, it may be the same as

a previously prescribed dose. It was agreed that clinically the best predictor of numeric daily dose was likely to be a person's previous prescriptions.

Several approaches were considered to handle missing numeric daily dose data:

1) Using the mode or median numeric daily dose: Most previous CPRD studies have used the mode or median numeric daily dose for oral corticosteroids where numeric daily dose is missing,[106,107] however this approach does not fully utilise the information available in the data.
2) Multiple imputation of numeric daily dose: This technique replaces each missing value with values representing the conditional distribution of the variable, based on observed data. These multiply imputed data sets are then individually analysed and the results are combined. In this instance, there were repeated measurements (i.e. several prescriptions), clustered within individual participants. This meant the data structure was multi-level.[108] Dealing with clusters would be statistically complex and is not handled by standard multiple imputation software commands, therefore this technique was not pursued.
3) An alternative multiple imputation approach was considered, whereby a single-variable summary of "numeric daily dose at other times" could be generated, perhaps using "last numeric daily dose" or "closest numeric daily dose". In this approach the data are no longer multi-level, therefore can be handled easily in STATA. The approach was taken in a recent paper by Fardet et al to impute daily dose.[109] However, use of this technique would not predict numeric daily dose for patients who only had a single prescription with missing numeric daily dose.

Another, computationally simpler, imputation approach called "Hot Decking" was instead used to address missing numeric daily dose. Hot Decking involves replacing missing data with observed data from a similar unit, or strata, for example patients of the same age and gender. The median numeric daily dose of the observed data, within the chosen strata, was used to replace missing numeric daily dose within that same strata. An algorithm was developed which reviewed each oral corticosteroid therapy record and imputed missing values, first where the strata were based on data within- persons, then where the strata were based on data from groups of patients. See Figure 3 for specific details.

Calculating duration and dose of oral corticosteroid prescriptions

Having cleaned the relevant variables and imputed missing data using the "hot decking" approach (see Figure 3), first the duration and dose of individual prescriptions were identified,

then, if patients had a series of prescriptions within a certain timeframe, continuous periods of use were defined.

The duration and daily dose of oral corticosteroid prescriptions were calculated as follows:

Duration = quantity ÷ numeric daily dose

Daily dose = dose per tablet x numeric daily dose

3.4.2.2. Inhaled corticosteroids

Definition

Inhaled corticosteroid (ICS) use 3 months prior to zoster diagnosis was identified. Prescriptions of any dose were included, as discrepancies are likely between the prescription and actual adherence, potentially making any calculated dose unreliable.

Background and data cleaning

Numeric daily dose for ICS represents the number of puffs a patient is directed to take on the inhaler per day. The variable "pack type" largely provided the number of puffs per inhaler, and the quantity variable represented the number of inhalers. Implausible values for ICS were identified; quantities > 4 (99% of ICS prescriptions had a quantity 1-4) were changed to the median value of one and numeric daily doses >40 (in other words, more than 40 puffs per day, as this was deemed a clinically plausible upper threshold) were changed to missing.

Missing data

Missing data for ICS were dealt with as follows;

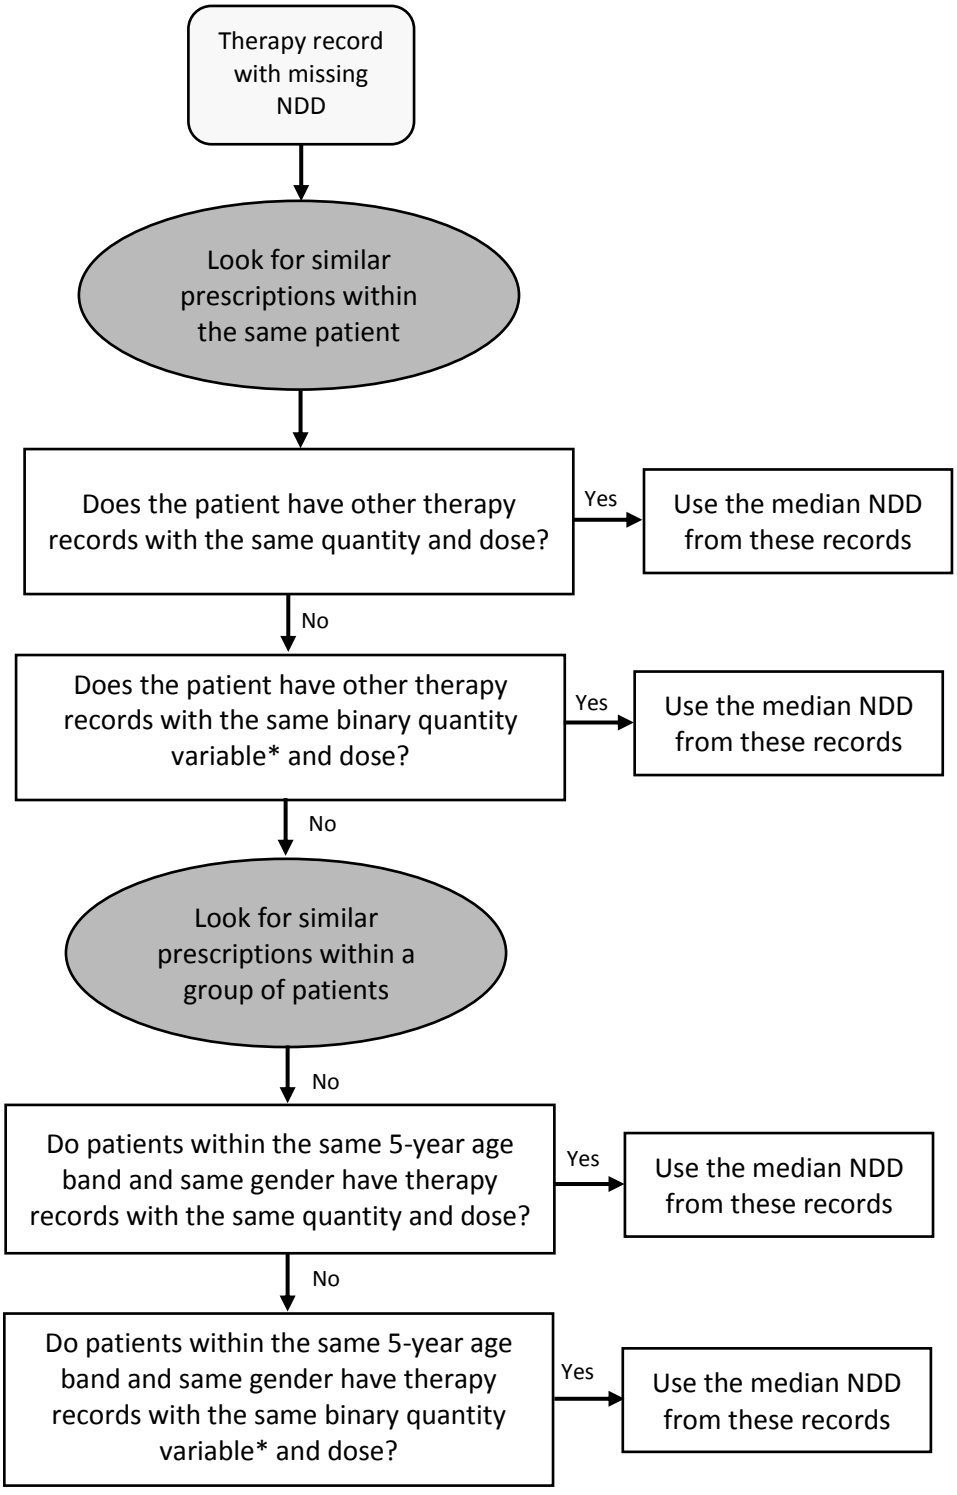
- Missing pack type: the most common pack type for the quantity and dose of each prescription, or if not available the median pack type value for all prescriptions of 200 was used.
- Missing numeric daily dose: the median value of 4 puffs per day was used.
- Missing quantity: the median value of 1 was used.

Calculating duration of inhaled corticosteroid prescriptions

Duration of individual inhaled corticosteroid prescriptions were calculated as follows:

(Quantity x pack type) ÷ numeric daily dose

Figure 3: Flow chart describing the "hot decking" imputation method used to impute missing values for numeric daily dose



Notes

(NDD, numeric daily dose, equivalent to number of tablets taken per day) *binary quantity variable refers to a variable that was created, which categorised quantity into low and high about the median quantity (42 tablets for oral corticosteroids, 36 tablets for other immunosuppressive drugs).

3.4.2.3. Other immunosuppressive therapies

In addition to corticosteroids, there are a number of other drugs which can cause immunosuppression, including: chemotherapy drugs such as antimetabolites, anthracyclines and alkylating agents; and drugs to treat autoimmune conditions such as anti-proliferative immunosuppressants.[110]

Definition

The primary definition of these *"other immunosuppressive therapies"* was any use in the month prior to zoster diagnosis. An alternative definition was also coded; which comprised any use in the three months prior to zoster diagnosis.

Data cleaning and imputing missing data

Where the variable quantity (total number of tablets prescribed) had a value of >1000 tablets, quantity was coded to missing. As with oral corticosteroid prescriptions, quantity was 99% complete and numeric daily dose had around 30% missing data. The hot-deck method was used to impute missing numeric daily dose, in the exact same way as for imputing numeric daily dose for oral corticosteroids (see Figure 3); the only difference being the binary quantity variable that was created used the median value 36 tablets (rather than 42 tablets).

Calculating duration of other immunosuppressive therapies

Duration was calculated as follows:

Quantity ÷ numeric daily dose

3.4.3. Autoimmune conditions

Three autoimmune conditions were defined: *RA, SLE,* and *IBD.* These disorders were defined through the presence of a Read code in CPRD any time prior to the zoster diagnosis.

3.4.4. Other clinical conditions

3.4.4.1. Diabetes

The diabetes definition required either: a definite diabetes diagnosis identified by Read codes in the CPRD clinical or referral files; or a possible diabetes Read code [e.g. self- monitoring of

blood glucose] with a subsequent diabetes-specific prescription [insulin or oral anti-diabetics]; or ≥2 diabetes drug prescriptions prior to the zoster diagnosis. Gestational diabetes and drug-induced diabetes were excluded as these are usually temporary, rather than chronic conditions.

Patients were categorised as type 1 or type 2 diabetes where possible. Distinguishing between type 1 and type 2 diabetes is not always possible using diabetes codes as patients are frequently given a non-specific code. Furthermore, where type of diabetes is assigned within a Read code, it has been found to be unreliable.[111] Therefore Read code data for type 1 and type 2 diabetes were not used, but instead age at first diagnosis, age at first treatment and, finally, treatment received was used to classify diabetes type, as in previous CPRD studies.[112,113]

Type 1 diabetes was assigned where:

- age at first diagnosis was ≤35 years and treatment ever was exclusively insulin; or
- patients received at least two insulin prescriptions ≤35 years, but had no diabetes diagnosis.

Type 2 diabetes was assigned where:

- age at first diabetes diagnosis was >35; or
- patients received exclusively oral anti-diabetics after 35 years of age.

Patients with age at diagnoses >35, but treated exclusively with insulin or any others not fitting into these categories were assigned as “Unknown type”.

3.4.4.2. Chronic obstructive pulmonary disorder

COPD patients were defined as anyone with a Read code for COPD prior to zoster diagnosis and aged ≥35 years at the time of diagnosis. Diagnostic READ codes used to identify COPD included chronic bronchitis, emphysema, chronic obstructive airways disease and chronic airflow limitation.[114]

Previous studies of COPD patients in UK primary care databases have used diagnostic codes or diagnostic codes[115-118] along with prescription data, for example having a minimum number of treatments following COPD diagnosis.[119] In this study, prescription data were not included because: 1) patients with mild COPD may not receive treatment (despite guidelines suggesting all COPD patients are given bronchodilators); 2) patients may be receiving treatment in

secondary care; 3) treatment is non-specific to COPD; prednisolone, the oral corticosteroid most commonly used in COPD treatment, is also used in other inflammatory and allergic disorders such as RA, asthma and IBD; bronchodilators and ICS are used in asthma treatment and other respiratory diseases; and finally 4) a recent validation study in CPRD of COPD diagnoses, concluded that use of COPD Read codes alone is sufficient to identify COPD patients.[120] Using medication in the definition of COPD does not appreciably improve the accuracy of the diagnoses.

The use of spirometry data were also considered, however, the above mentioned validation study found that using spirometry recordings did not significantly improve the accuracy of COPD diagnoses.

3.4.4.3. Asthma

Although asthma can be chronic, patients may not continuously experience symptoms. Therefore it was decided to identify patients who were likely to have "active" asthma at the time of zoster diagnosis. Patients were considered to have "active" *asthma* if they had an asthma diagnosis prior to zoster diagnosis and additionally an asthma-related prescription within the 12 months prior to the zoster diagnosis. This definition matches the criteria required to be on the asthma register in the UK.[121] Patients with a COPD diagnosis ever in their medical history were also unable to be defined as asthma patients; differentiating between these two conditions is challenging and this criteria helped exclude COPD patients misdiagnosed as asthma. Asthma related prescriptions included the following respiratory drugs; short and long-acting beta-2 agonists and short and long-acting antimuscarinics, ICS, cromoglycates and nedocromil, theophyllines, leukotriene receptor agonists and omalizumab.

3.4.4.4. Chronic Kidney Disease

CKD was defined as any patient with a clinical diagnosis of mild, moderate or severe CKD, or evidence of having received kidney dialysis, any time prior to zoster diagnosis. CKD diagnosis is mostly based on serum creatinine tests which can be used to obtain the glomerular filtration rate (how much blood passes through the kidneys each minute), and estimate the stage of kidney disease. However, these tests were not included in the definition of CKD as certain groups, such as elderly patients with diabetes, may be more likely to be tested, potentially leading to a non-representative sample of CKD patients.

3.4.4.5. Depression

As depression tends to occur in episodes, the aim was to identify recent depression. In this study, depression was defined as any patient with a Read code within one year prior to the zoster diagnosis for new onset or current symptomatic depression. Read codes for both diagnoses and symptoms were included. Symptoms were included, in addition to diagnoses, due to the trend post-2004 of using symptom, rather than diagnosis codes, in UK primary care.[122] Antidepressants were not used in the definition of depression as these drugs are used in a wide range of other disorders, including the management of chronic pain and stroke recovery.

3.4.5. Demographic factors

3.4.5.1. Age

All "acceptable" patients in CPRD have a year of birth, and some patients born after 1990 have a month of birth. Where month of birth was missing, July was used, and all patients were allocated a birth date of the 1st of the month, as day of birth is not available.

3.4.5.2. Gender

Gender is provided in CPRD and there was no missing information for gender. Patients with indeterminate gender were excluded (in the January 2012 CPRD build, 0.0001% were indeterminate gender).

3.4.5.3. Socioeconomic status

Socioeconomic status (SES) was analysed using quintiles of the Index of Multiple Deprivation (IMD) score. The IMD combines a number of indicators, chosen to cover a range of economic, social and housing issues, into a single deprivation score.[123,124] IMD is available at the practice and patient level. The practice postcode or patient's home postcode is mapped at the lower level super output level to the corresponding IMD score; a low quintile represents the least deprived, while a higher quintile the most deprived. Patient level IMD data are available for patients registered at English practices agreeing to link medical records with other databases and who have a valid and linkable postcode in their medical records. The papers on zoster risk factors (chapter 4) and antiviral use (chapter 5) used the IMD dataset released in 2007, whilst the paper on PHN risk factors (chapter 7) used the IMD dataset released in 2010. Practice level

IMD was available for all practices within the IMD 2010 dataset, whereas only for English patients in the IMD 2007 dataset.

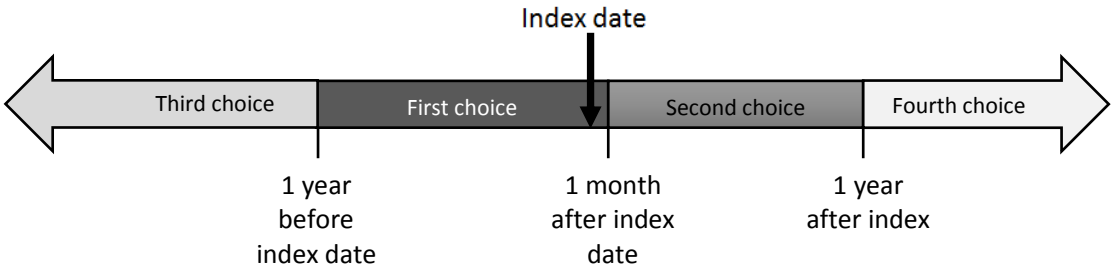
3.4.6. Lifestyle data

3.4.6.1. Smoking status

Smoking was defined at zoster diagnosis using three categories; non-smoker, current smoker and ex-smoker. Data were derived from: 1) medical Read codes such as "tobacco dependence in remission" and "stopped smoking"; and 2) data from structured data fields in the additional details file, specifically entity type number four records information on smoking, including the patients smoking "status" (yes, no or ex) and the "number of cigarettes per day" smoked. These data were extracted for each patient along with the date the status was assigned.

Smoking status was then classified by the algorithm shown in Figure 4.

Figure 4: Algorithm used to define BMI, smoking and alcohol status



Note: the nearest record to the index date from the first choice period was taken if available, otherwise from the second choice period and so on. If patients had any evidence of smoking or alcohol prior to zoster diagnosis, but were defined by the algorithm as a non-smoker or non-drinkers, they were reclassified as ex-smokers or ex-drinkers.

3.4.6.2. BMI category

BMI is a metric used to classify people as under- or overweight. It is derived from patients weight in kilograms / (height in meters)^2. In this study BMI was defined at zoster diagnosis, according to adult BMI cut-offs defined by the WHO, as underweight (BMI <18.5), healthy weight (BMI 18.5-24.9), overweight (BMI 25+) or obese (BMI ≥30).

Height and weight are recorded opportunistically in UK primary care and are contained in the CPRD additional details files, in entity types 104 and 140. Data cleaning was based on that described in the paper by Bhaskaran et al on BMI recordings in CPRD.[125] Any records taken when the patient was <16 years old were dropped, as the patient would still be growing.

Implausible values were excluded, specifically height records <4 and >7 foot were dropped, and weight records <20 kilograms were dropped. For each weight record, a BMI was calculated using first, height recorded on that day, otherwise, last observation of height, or if no previous height records were available, then first future height.

BMI status was then classified by the algorithm shown in Figure 4.

Read codes exist classifying patients by BMI category, however they are very rarely used (around 3% of patients have a clinical code that would enable classification into WHO BMI categories),[125] therefore Read codes were not incorporated into the definition of BMI.

3.4.6.3. Alcohol use

Alcohol use was defined at zoster diagnosis and classified as non-drinker, ex-drinker, or current drinker using: 1) medical Read codes, such as "alcohol problem drinking"; and 2) data from structured data fields in the additional details file, specifically entity type 5 records data on alcohol use, including the patients alcohol "status" (yes, no or ex) and the number of alcohol "units per week" consumed.

Alcohol status was then classified by the algorithm shown in Figure 4.

3.4.7. Characteristics of the acute zoster episode

3.4.7.1. Antiviral use during acute zoster episode

Antiviral medications are recommended for all immunosuppressed and some immunocompetent patients following zoster diagnosis. Guidelines specify they must be given within seven days of a zoster diagnosis.[126] Therefore antiviral medications given up to a week following zoster diagnosis were identified from CPRD therapy records. Three different antivirals were searched for; aciclovir, famciclovir and valaciclovir.[3] If zoster patients had two different antivirals prescribed on the same day, this was recorded.

3.4.7.2. Site of zoster

The site of zoster is not routinely recorded in CPRD or HES. However, some Read and ICD codes which identify zoster also contain the location of zoster, for example, "Herpes zoster with ophthalmic complication". The level of detail contained in the diagnostic codes allowed

zoster patients to be categorised as, “ophthalmic zoster”, “non-truncal zoster” or “site unspecified”.

As patients may have more than one interaction with their GP or hospital regarding their zoster episode, particularly for complicated zoster involving the eye, all zoster codes in the year following the first zoster diagnosis were extracted from CPRD and HES, and their site determined. Site was then assigned in order of priority; ophthalmic, non-truncal and finally site unspecified.

In the study of PHN risk factors (described in chapter 7) ophthalmic zoster was identified through a revised algorithm, to improve identification of ophthalmic zoster. In a US study of an administrative data source (specifically, all adult residents of Olmsted County, Minnesota, aged ≥22 years seeking medical care for zoster between 1996 and 2001) just 10% of patients whose full medical records reported zoster affecting the eye, also had an ICD-9 code indicating an ophthalmic complication. In the study described in chapter 7, ophthalmic zoster was therefore additionally defined as patients with non-specific zoster, plus a diagnosis of, or treatment for, acute eye infection (such as keratitis or conjunctivitis) within 2 weeks of zoster onset or from records of first-ever specific chronic eye conditions known to be associated with zoster (such as, conjunctival scarring or episcleritis), within 3 months after zoster onset. This was in line with a previous study in CPRD.[5]

3.5. Chapter summary

Data sources and variable definitions

- This study utilises data from a UK primary care database called CPRD, which holds data on over 12 million patients and is largely representative of the UK population. The study also uses a linked secondary care database called HES, which holds data on all hospital admissions throughout England.
- Zoster was defined through the presence of Read codes in CPRD and ICD-10 codes in HES.
- PHN was defined as pain for at least 90 days following zoster diagnosis, and identified through the presence of diagnosis codes in CPRD and HES, along with prescription data in CPRD.
- The other explanatory variables utilised in this thesis were identified from data in CPRD, and included: severely immunosuppressive conditions, immunosuppressive therapies, autoimmune conditions (RA, SLE and IBD), other clinical conditions (diabetes, COPD, asthma, CKD and depression), demographic factors (age, gender and SES), lifestyle data (BMI category, smoking and alcohol use) and characteristics of the acute zoster episode (antiviral use during acute zoster and site of zoster rash).

Chapter 4: Quantification of risk factors for zoster: population based case-control study

4.1. Introduction

Understanding the risk factors for zoster is important when planning vaccination campaigns. A large case-control study was therefore carried out to quantify the effects of various proposed risk factors for zoster and explore whether their effects differed by age group. Such investigations may help to identify any groups of patients at high risk of zoster, who are not currently targeted for vaccination.

This research, which was published in the British Medical Journal, is presented below, along with its published appendices which were too detailed for the main paper. The paper is followed with some additional information on: 1) how controls were selected in this study; 2) the relative risk of zoster according to smoking, BMI and alcohol status; and 3) additional biological evidence indicating impaired cell-mediated immunity, associated with the risk factors of interest.

Abstract

Objectives To quantify the effects of possible risk factors for herpes zoster at different ages.

Design Case-control study.

Setting UK Clinical Practice Research Datalink primary care data.

Participants 144 959 adults diagnosed with zoster between 2000 and 2011; 549 336 age, sex, and practice matched controls.

Main outcome measures Conditional logistic regression was used to generate adjusted odds ratios to estimate the strength of association of each potential risk factor with zoster and assess effect modification by age.

Results The median age of the cases and controls was 62 years. Factors associated with increased risk of zoster included rheumatoid arthritis (3111 (2.1%) *v* 8029 (1.5%); adjusted odds ratio 1.46, 99% confidence interval 1.38 to 1.55), inflammatory bowel disease (1851 (1.3%) *v* 5118 (0.9%); 1.36, 1.26 to 1.46), chronic obstructive pulmonary disease (6815 (4.7%) *v* 20 201 (3.7%); 1.32, 1.27 to 1.37), asthma (10 243 (7.1%) *v* 31 865 (5.8%); 1.21, 1.17 to 1.25), chronic kidney disease (8724 (6.0%) *v* 29 437 (5.4%); 1.14, 1.09 to 1.18), and depression (6830 (4.7%) *v* 22 052 (4.0%); 1.15, 1.10 to 1.20). Type 1, but not type 2, diabetes showed some association with zoster (adjusted odds ratio 1.27, 1.07 to 1.50). The relative effects of many assessed risk factors were larger in younger patients. Patients with severely immunosuppressive conditions were at greatest risk of zoster—for example, patients with lymphoma (adjusted odds ratio 3.90, 3.21 to 4.74) and myeloma (2.16, 1.84 to 2.53), who are not eligible for zoster vaccination.

Conclusions A range of conditions were associated with increased risk of zoster. In general, the increased risk was proportionally greater in younger age groups. Current vaccines are contraindicated in people at the greatest risk of zoster, highlighting the need for alternative risk reduction strategies in these groups.

Introduction

Herpes zoster (commonly known as shingles) is caused by the reactivation of latent varicella zoster virus when specific cell mediated immunity becomes compromised. It is a common disease in older people,[1] with a lifetime risk of up to 30% rising to 50% among those living to 85 years.[2] Zoster typically presents as a painful unilateral vesicular dermatomal rash that causes acute morbidity lasting two to four weeks.[3] A severe complication—postherpetic neuralgia—although uncommon in patients aged under 50, develops in 12% of zoster patients aged 50 years or over[1 4]; it causes intense pain that can last from months to years and is associated with considerable impairment of quality of life.

A live vaccine that reduces the risk of zoster and postherpetic neuralgia has recently been developed.[4] The vaccine is licensed in peoople aged over 50 years. In the United States and Australia, it is recommended in people aged 60 years or over. In the United Kingdom, it is routinely available for patients aged 70, with a catch-up campaign for 72-79 year olds (on the basis of cost effectiveness studies[5]); the current catch-up cohort is those aged 79. Table 1⇓ shows some examples of recommedations on vaccination in major countries. As the zoster vaccine is expensive, targeting vaccination towards groups at high risk of zoster is necessary. Age is the most important risk factor for zoster and postherpetic neuralgia, so it drives vaccination policies. The incidence of zoster rises from 3.5 per 1000 person years among 50-54 year olds to 7.1 per 1000 person years among 75-79 year olds in the UK.[6] However, whether people with other risk factors, particularly in younger age groups, might also benefit from vaccination is not clear.

Several clinical conditions not listed as contraindications for the zoster vaccine have been associated in some studies with an increased risk of zoster; these include autoimmune conditions such as rheumatoid arthritis,[7] systemic lupus erythematosus,[8]

and inflammatory bowel disease,[9] and chronic conditions such as diabetes mellitus,[10 11] chronic obstructive pulmonary disease,[11 12] chronic kidney disease,[13-15] asthma,[16] and depression.[2 17] Large, adequately powered studies investigating the association of these conditions with zoster are lacking.

This study therefore aimed to quantify the effects of various proposed risk factors for zoster and explore whether their effects differ by age group, to help to identify any groups of patients at high risk who are not currently targeted for vaccination. We aimed to add to the existing literature by using a very large data source and a consistent methodological approach to help comparison between various risk factors.

Methods

We did a matched case-control study to quantify the effects of a range of individual level factors on the risk of zoster in a general population.

Data source

This study used data from the UK Clinical Practice Research Datalink, a primary care database of anonymised patients' records containing complete prescribing and diagnostic information and feedback from hospital referrals. Clinical diagnoses are coded in the Clinical Practice Research Datalink with Read codes.[18] It is one of the largest sources of continuous patients' records in the world, containing data on approximately 7% of the UK population, and is broadly representative of patients' and practices' characteristics in the UK.[19] Sixty per cent of patients in the Clinical Practice Research Datalink have data available in the Hospital Episode Statistics database, which is a linked computerised database of hospital attendances in England from 1997.

Selection of cases

The base study population consisted of all patients aged 18 years or over, under follow-up between 1 January 2000 and 31 December 2011, with no evidence of previous zoster (no codes for zoster or postherpetic neuralgia before the start of follow-up). We identified zoster cases by using the Clinical Practice Research Datalink and Hospital Episodes Statistics. Cases in the Clinical Practice Research Datalink were those with a zoster Read code and at least 12 months' follow-up before a first diagnosis of zoster, to exclude past cases of zoster recorded retrospectively after registration at a general practice.[20] Incident zoster in Hospital Episodes Statistics was identified by ICD-10 (international classification of diseases, 10th revision) codes (B02, B02.0, B02.1, B02.31, B02.7, B02.8, B02.9, G53.0) that appeared in the primary diagnosis field; we excluded patients with these codes recorded in secondary diagnosis fields, as this could reflect either incident zoster or sequelae of past zoster. For cases identified in Hospital Episodes Statistics, we took the date of hospital admission as the index date. If zoster was identified in both Hospital Episodes Statistics and the Clinical Practice Research Datalink, we took the earliest recorded zoster diagnosis as the index date.

Selection of controls

We identified all potential controls for each case and used incidence density sampling to select up to four controls per case at random.[21] Controls were registered with the practice at the index date of the case and for at least 12 months before and were matched to cases by practice, sex, and age (within 1 year). We selected controls before their exposure status for other risk factors was known. By matching on practice, we controlled for practice level socioeconomic status. Controls took the index date of their matched case. Controls had no history of zoster or postherpetic neuralgia at the index date, but they could go on to have zoster and therefore also be included as a case.[22] Controls with no contact with their practice (that is, no consultation record of any kind, including repeat prescriptions and face to face or telephone consultations) any time from six months before to 12 months after the index date were assumed inactive in the database and excluded.

Risk factors

Information on risk factors was based on records entered in the Clinical Practice Research Datalink any time before the index date. For each risk factor, we developed a definition and a list of relevant Read codes. A clinician reviewed all code lists, and these are available on request. Patients without Read codes for a clinical condition were assumed not to have the condition.

Key risk factors of interest

Our key risk factors of interest were rheumatoid arthritis, systemic lupus erythematosus, inflammatory bowel disease, chronic obstructive pulmonary disease, asthma, chronic kidney disease, depression, and diabetes (overall and by type) (see appendix section A for a full descriptions of how these risk factors were identified).

Severe immunosuppression

Our models included severely immunosuppressive conditions determined by the Advisory Committee on Immunization Practices to be contraindications to vaccination—namely, recent history (less than two years before index date) of leukaemia, lymphoma, or bone marrow transplant, or any history of HIV, haematopoietic stem cell transplantation, myeloma, or "other unspecified cellular immune deficiencies" (for example, pancytopenia).[23] We also included use of immunosuppressive treatment; we extracted all relevant prescriptions before the index date and calculated duration of prescription (using data on quantity of tablets prescribed and numeric daily dose). We defined oral corticosteroid exposure as a 14 day course of high dose (≥20 mg/day) oral corticosteroids in the month before the index date. We included exposure to other immunosuppressive treatments in the month before the index date as an additional covariate (see appendix section A for further details).

Other characteristics

Other characteristics of patients included smoking (ex-smoker, current smoker, non-smoker), alcohol consumption (non-drinker, current drinker, ex-drinker), and body mass index (underweight (<18.5), normal weight (18.5-24.9), overweight (≥25), obese (≥30)) (see appendix section A for further details). We captured exposure to inhaled corticosteroids within three months before the index date (see appendix section A for further details), as some evidence suggests that they may increase the risk of zoster.[24] We compared follow-up time (in years) for cases and controls, to check that the opportunity to record the exposures of interest in the two groups was equal.[25]

To explore whether the association between our risk factors of interest and zoster could be affected by ascertainment bias (that is, visiting a general practice for the risk factor may increase the likelihood of receiving a diagnosis of zoster), we investigated the association between zoster and treated epilepsy (an epilepsy Read code before index date and an epilepsy treatment (*British National Formulary* chapter 4.8.1) 12 months before the index

date). Epilepsy is a chronic condition requiring high level healthcare use[26]; it is not thought to be associated with zoster.

Statistical analysis

We described the characteristics of the study population by case-control status. The analysis accounted for the matched design by using conditional logistic regression, so all odds ratios accounted for the matching factors of age (within 1 year), sex, practice, and calendar time. Initially, we calculated univariable odds ratios to estimate the strength of association of each potential risk factor with zoster; 99% confidence intervals were generated to account for multiple testing and reduce the chance of picking up small and clinically unimportant associations. We then did multivariable analyses on patients with complete data for all variables (see also below for approach to missing data).

We investigated a potentially effect modifying role of age at diagnosis (index) date by calculating stratum specific odds ratios for each variable in the multivariable model by age groups (>50 years, 50-59 years, 60-69 years, and ≥70 years). We added interaction terms between age and other risk factors one at a time into the multivariable regression model and used likelihood ratio tests to investigate interactions.

To quantify the effect of our assessed risk factors, we estimated the age specific absolute rate of zoster for each factor by multiplying the age specific effect estimates by the age specific rate of zoster in the general population in 2010. We estimated the age specific general population rates within the Clinical Practice Research Datalink by dividing the number of incident cases of zoster in 2010 by the total person time contribution of the population at risk in that year, which included all patients in the Clinical Practice Research Datalink with at least one year of follow-up and no history of zoster.

We then evaluated to what extent combinations of risk factors could lead to a high risk of zoster, specifically within age groups not targeted for vaccination. We calculated the predicted risk of zoster for each person by summing the coefficients for their risk factors from the final model and multiplying their predicted odds ratio by the age specific rate of zoster in the general population. We were thus able to determine the number of cases aged under 70 but with a predicted risk of zoster equal to or higher than that of the general population aged at least 70 years (vaccination is currently offered to 70 and 79 year olds in the UK). We repeated this analysis with a 60 years age cut-off, to reflect vaccination policy from different countries. We restricted these calculations to people without severely immunosuppressive conditions.

Sensitivity analyses included use of a wider definition of exposure to oral corticosteroids and other immunosuppressive treatment (anyone exposed three months before the index date). We used multiple imputation by chained equations to account for missing data (11% of patients had missing data for alcohol or smoking).[27] The imputation model included all covariates from the main outcome model, together with matching variables of age and sex, and extra comorbidities as additional markers of alcohol or smoking related diseases. We created five imputed datasets and combined them for analysis. We further adjusted for patient level socioeconomic status in the subgroup of patients registered at English practices for whom these data were available (see appendix sections B-D for further details). We applied two different definitions of an "active" control. Firstly, we considered controls to be inactive if they had no contact with their general practice during any time from one year before to two years after the index date. Secondly, we considered controls to be inactive if they had not consulted their general practice in the previous three years. Finally, we calculated the mean yearly consultation rate before the index date (by dividing the total number of face to face or telephone consultations during follow-up by the total years of follow-up before the index date) among patients with our risk factors of interest and among patients with epilepsy.

Results

We identified a total of 145 397 incident cases of zoster. After matching, we removed inactive controls (n=27 928; 4.8% of all 577 264 matched controls). We excluded a small number of cases, as they had no eligible controls (n=438; 0.3%), largely owing to advanced age, leaving 144 959 cases.

Table 2⇓ shows descriptive details of the cases and controls; 59.4% of cases and 61.0% of controls were female (the higher proportion among controls was due to the variable number of controls per case). The median age at diagnosis of zoster was 62 (interquartile range 48-73) years for cases and 62 (49-74) years for controls. Approximately 45% of zoster cases occurred in patients under 60 years and 65% in those under 70 years. Registered follow-up time before the index date was equivalent in cases and controls (8.6 (4.3-12.1) years).

Table 3⇓ shows the proportion of cases and controls with our key risk factors of interest and other covariates. The strongest risk factors for zoster were the severely immunosuppressive conditions, although their overall prevalence was low—2.8% of cases and 1.2% of controls (table 3⇓). Odds ratios varied from 1.78 to 13.46, although the latter estimate (for haematopoietic stem cell transplantation) had a particularly wide 99% confidence interval, as it was based on only 29 exposed patients.

Among our key risk factors of interest, systemic lupus erythematosus had the strongest relative risk of zoster (adjusted odds ratio 1.72, 99% confidence interval 1.45 to 2.04) (table 3⇓), but the condition was very rare (0.3% of cases and 0.1% of controls). The risk of zoster was increased by more than 30% among patients with rheumatoid arthritis (adjusted odds ratio 1.46, 1.38 to 1.55) and chronic obstructive pulmonary disease (1.32, 1.27 to 1.37). Asthma, chronic kidney disease, and depression were associated with a greater than 10% increased risk of zoster. Although no association existed between zoster and diabetes overall (adjusted odds ratio 1.02, 0.99 to 1.05), we found strong evidence that patients classified as having type 1 diabetes were at increased risk of zoster (1.27, 1.07 to 1.50).

To assess whether some of the overall effect of these conditions was mediated by their treatments, we additionally adjusted for immunosuppressive treatments and inhaled corticosteroids (table 3⇓, final column). The associations between zoster and rheumatoid arthritis, systemic lupus erythematosus, inflammatory bowel disease, chronic obstructive pulmonary disorder, and asthma were attenuated after adjustment but did not disappear. Among conditions not commonly treated with these drugs (chronic kidney disease, depression, and diabetes), the association did not vary after this additional adjustment.

Treated epilepsy, not expected to be associated with zoster, was marginally more common among cases than controls (1420 (0.98%) *v* 5142 (0.94%)). We found little evidence of association with zoster in crude (odds ratio 1.05, 0.97 to 1.14) or adjusted analyses (1.06, 0.97 to 1.15), suggesting that other associations observed in this study are unlikely to be explained by ascertainment bias.

We explored how the effect of our risk factors varied by age (tables 4⇓ and 5⇓). We found some evidence of age interaction.

In general, the relative effects of these risk factors on zoster decreased with increasing age. For example, among patients with chronic kidney disease the odds ratio point estimate was 1.53, 1.21, and 1.11 among patients aged 18-49, 50-59, and 60-69 years respectively.

To quantify the effect of our key risk factors of interest, particularly among age groups not targeted for vaccination, we estimated absolute rates of zoster (table 6⇓). The rates remained low among patients aged 18-49 years (for example, for those with rheumatoid arthritis: 3.51 (99% confidence interval 2.40 to 5.13) per 1000 person years), despite the high relative risks in this age group. The absolute rates of zoster among patients aged 60-69 years were relatively high, particularly for those with chronic obstructive pulmonary disease and rheumatoid arthritis.

We calculated the predicted risk of zoster among 143 620 zoster cases (having excluded 1339 patients with severely immunosuppressive conditions) on the basis of their risk factor profile. Among these cases, 40 409 (28.1%) had at least one risk factor of interest. Of 97 789 zoster cases aged under 70 years, 3619 (3.7%) had a predicted risk as high as that for the general population aged 70 or over; 643 (0.96%) of 67 000 patients under 60 years had a predicted risk as high as those aged 60-69 years.

Sensitivity analyses imputing missing data for smoking and alcohol (see appendix section B), using different definitions for immunosuppressive treatment (see appendix section C), adjusting for patient level socioeconomic status (see appendix section D), and applying different definitions of an active control (see appendix section E) did not change the study findings. The consultation rate was similar among patients with epilepsy and those with our risk factors of interest (see appendix section F).

Discussion

In this large matched case-control study, a range of conditions were associated with increased risk of zoster, including rheumatoid arthritis, systemic lupus erythematosus, inflammatory bowel disease, chronic obstructive pulmonary disease, asthma, chronic kidney disease, type 1 diabetes, and depression. The relative effects of many of these risk factors were larger among younger patients. This raises the question of whether vaccination of certain younger, high risk groups may be beneficial; cost effectiveness studies, also considering the risk of postherpetic neuralgia, would be needed to answer this question. Among a wide range of risk factors, people with contraindications to currently available vaccines were at the highest risk of zoster, highlighting the need to identify strategies to reduce the risk of zoster among these groups.

Strengths and limitations of study

This large study included all incident cases of zoster in the Clinical Practice Research Datalink over an 11 year period, providing high power to detect small effects, except for rare potential risk factors. We assessed a wide range of factors, allowing adjustment for many of the known as well as potential confounders, in addition to exploring interactions with age, which is of key public health relevance in terms of vaccination policy.

The study may be subject to ascertainment bias; regular general practice visits for a chronic condition such as diabetes may increase the likelihood of receiving a zoster diagnosis. However, we believe that most zoster cases would present to their general practice, owing to the extensive rash and considerable pain associated with zoster and free general practice attendance in the UK.[28] A survey about immunisation practices in the United States among people aged 60 and over found that 95% of those who knew they had zoster sought care.[29] Furthermore, we found little evidence to suggest that patients with epilepsy (who were visiting their general practice as frequently as patients with our risk factors of interest) were at increased risk of zoster.

As with any observational study, residual confounding may be present. For example, exposure to varicella contacts, hypothesised to naturally boost varicella zoster virus specific immunity in people with latent varicella zoster virus infection and thus protect against zoster,[30] was not available.

Some misclassification of zoster is possible. In UK primary care, diagnosis of zoster is clinically based with no laboratory testing. Validation of zoster diagnoses in primary care in the Netherlands found that 90.8% of cases had raised antibodies indicating recent zoster infection, suggesting that diagnosis of zoster has a high positive predictive value.[31] The frequency with which general practitioners wrongly reject the diagnosis of zoster has not, however, been investigated; this may be more common among younger patients in whom zoster is uncommon. However, the most common misclassification of zoster is as recurrent herpes simplex, which very rarely presents in a dermatomal distribution.[32] Zoster is typically a straightforward clinical diagnosis, so the extent of misclassification is likely to be minimal. Any misclassification is likely to be non-differential with respect to exposure status, thus leading to an underestimation of associations.

Finally, excluding "inactive" controls to remove patients who would not attend their general practice if they did develop zoster, may have resulted in healthier controls not being included and led to an underestimation of the odds ratios.

Comparison with other studies

The strength of association between the autoimmune conditions in this study and risk of zoster is broadly in line with previous studies.[7-9 33] The increased risk associated with these conditions may partly reflect exposure to immunosuppressive drugs, as well as the conditions themselves. When we adjusted for immunosuppressive treatments, the increased risk of zoster was attenuated, suggesting that these drugs contribute to the overall increased risk of zoster in these patients.

The effect of chronic obstructive pulmonary disease is also consistent with previous studies.[11 12] After adjustment for oral and inhaled corticosteroids commonly used to treat chronic obstructive pulmonary disease, the association reduced in these patients, again suggesting that these treatments add to their overall risk of zoster. Larger associations between zoster and depression have been reported.[11 17 34] No consensus exists on how to capture depression in electronic records; previous studies used different definitions, which may contribute to the varied findings. For example, a matched case-control study using commercial claims and encounters data in the United States found a higher risk of zoster among patients aged over 65 with depression (odds ratio 1.52, 95% confidence interval 1.46 to 1.58) but only included very severe cases (depressive disorder, chronic depressive personality disorder, or dysthymic disorder).[11] The association of zoster with chronic kidney disease was also smaller than previous studies have suggested.[15]

The risks of zoster are reportedly increased in patients with diabetes of unspecified type.[10 11 34 35] We found some evidence that type 1, but not type 2, diabetes was associated with an increased risk of zoster (although differentiating between type was not based on diagnostic codes, so misclassification is

possible). Patients with type 1 diabetes may be at higher risk of zoster owing to the immune dysregulation resulting from autoimmune pathogenesis.[36] The lack of effect found with type 2 diabetes must be interpreted cautiously, as negative confounding by ethnic group is possible; the type 2 diabetes population may have included South Asian patients (known to be at lower risk of zoster[2 37] and higher risk of diabetes). Ethnicity is poorly recorded for older patients not recently registered in the Clinical Practice Research Datalink, so we could not capture this characteristic.

The observed increased risks of zoster suggest that all these conditions are associated with some cell mediated immunosuppression. Disease induced immunosuppression has been proposed in chronic obstructive pulmonary disease and asthma patients,[38-42] although long term exposure to corticosteroids in these patients is also likely to contribute to immunosuppression. Patients with chronic kidney disease are known to have immune dysfunction,[43] particularly when the disease reaches end stage. For depression, stress may increase the risk of zoster as it affects several neuroendocrine functions that can affect cell mediated immunity,[44] and depression itself has been associated with poorer zoster immunity.[45 46]

Conclusions and policy implications

Severe immunosuppression is known to be associated with an increased risk of zoster.[11 47-49] What this study has highlighted, however, is that the strongest clinical risk factors for zoster are contraindications to its vaccine; the people arguably in most need of protection against zoster cannot currently benefit from vaccination. Alternative risk reduction strategies in these patients would help those at greatest risk of this disease and its complications.

Another important consideration regarding vaccination policy is whether the risk factors for zoster are also risk factors for zoster's main morbidity, postherpetic neuralgia. To date, very few studies have looked at this research question, and most have been underpowered. The role of severe immunosuppression as a risk factor for postherpetic neuralgia is inconclusive; three studies found that "general" immunosuppression was a risk factor for postherpetic neuralgia,[35 50 51] whereas another study found no association.[52] Autoimmune conditions have scarcely been assessed; one large cohort study in 34 280 zoster patients identified in Taiwanese health insurance records found that those with systemic lupus erythematosus were at greater risk of postherpetic neuralgia (rate ratio 2.27, 95% confidence interval 1.75 to 2.94).[35] Three studies found point estimates for the association between diabetes and postherpetic neuralgia greater than one in multivariate analyses, although the evidence was insufficient to confirm the association.[51 53 54] Some evidence suggests that depression is associated with postherpetic neuralgia.[55] Larger studies assessing these and other risk factors for postherpetic neuralgia are needed to improve our understanding of the risk factors for postherpetic neuralgia.

This study also raises the question of whether younger age groups at high risk of zoster may benefit from vaccination. Most cases of zoster occur in age groups too young for vaccination; this is because vaccination policy considers the risk of both zoster and postherpetic neuralgia, which is very uncommon in patients under 50. Deciding whether vaccination of groups of patients currently too young for vaccination would be cost effective will therefore require additional research on the risk factors for postherpetic neuralgia, specifically among patients aged under 50.

Our study has identified a range of conditions that are associated with an increased risk of zoster, raising the question of whether targeted zoster vaccination of specific high risk groups at younger ages is warranted. However, this study has also shown that patients at the greatest risk of zoster are not currently eligible to receive the vaccine.

What is already known on this topic

A new herpes zoster vaccination campaign introduced in the United Kingdom in September 2013 is focused on older people only

Recent literature has suggested that a range of clinical conditions are associated with an increased risk of zoster, raising the possibility that some younger people may be at high risk

However, large, highly powered studies investigating the association of these clinical conditions with zoster are lacking

What this study adds

Conditions associated with increased risk of zoster included rheumatoid arthritis, systemic lupus erythematosus, inflammatory bowel disease, chronic obstructive pulmonary disease, asthma, chronic kidney disease, type 1 diabetes, and depression

The increased risks were generally greater among younger age groups

The strongest risk factors are contraindications to vaccination, emphasising the need for alternative risk reduction strategies among these groups

Tables

Table 1| Vaccine recommendations in United Kingdom, United States, Canada, Australia, and Sweden

Country	Groups recommended to receive vaccine	Contraindications
United Kingdom	People aged 70 years, with catch-up campaign for 72-79 year olds (current catch-up cohort is 79 year olds)	People with primary or acquired immunodeficiency state; active untreated tuberculosis infection; confirmed anaphylactic reaction to previous dose of varicella vaccine or any component of vaccine; pregnant women; people receiving immunosuppressive treatment (including high dose corticosteroids)
United States	Recommended for people aged ≥60 years	People with history of anaphylactic/anaphylactoid reaction to any component of vaccine; history of primary or acquired immunodeficiency state; people receiving immunosuppressive treatment, including high dose corticosteroids; women who are or may be pregnant
Canada	Recommended for people aged ≥60 years; also available for those aged 50-59 years	People with anaphylactic hypersensitivity to any of vaccine's componenets; congenital or acquired immune deficiency; active untreated tuberculosis; use of immune suppressive drugs; pregnant women; people with certain acute illnesses
Australia	Recommended for people aged ≥60 years; also available for those aged 50-59 years	People with anaphylactic hypersensitivity to any of vaccine's componenets; those receiving high dose systemic immunosuppressive treatment (such as chemotherapy, radiation therapy, or oral corticosteroids); people with malignant conditions of reticuloendothelial system; any person with similar immunosuppression due to disease or treatment
Sweden	Recommended for people aged ≥50 years	People with weakened immune systems due to drug treatment or other health conditions; allergy to gelatin or neomycin; moderate or severe illness; women who are or may be pregnant

4.3. Published appendices

Appendix (as published)

A: Further detail on defining risk factors
B: Dealing with missing data
C: Different definition of exposure to oral corticosteroids and immunosuppressive conditions
D: Association of various risk factors with zoster, after additionally adjusting for patient-level socioeconomic status
E: Different definitions of "active" controls
F: Consultation rate among patients with risk factors of interest

A: Further detail on defining risk factors

This information has been removed, as all risk factor definitions have been described in chapter 3, "Data sources and variable definitions". For transparency, the information can be found in Appendix III.

B: Dealing with missing data

We used multiple imputation to account for missing data. Missing data was present for alcohol and smoking. In total, 89% of patients had complete data for all variables. To maximise the use of the data while properly incorporating the extra uncertainty arising due to missing data, multiple imputation by chained equations[127] was used to impute missing values for alcohol and smoking from multinomial models. The imputation model included all covariates from the main outcome model, together with the matching variables age and sex. We also included extra comorbidities, identified using medical Read codes, to look for additional markers of alcohol or smoking related diseases. These included: stroke, peripheral artery disease, angina (stable and unstable), acute coronary syndrome, congestive heart failure, myocardial infarction, hypertension and alcoholic liver disease (including portal hypertension) and pancreatitis. Five imputed datasets were created and combined for analysis. Distributions of imputed values were visually checked for comparability with the observed data.

Table B1: Relative risk of zoster in patients with various risk factors, using a multiply imputed dataset

	Adjusted OR (99% CI)*
Clinical conditions	
Rheumatoid Arthritis	1.47 (1.39 to 1.56)
Systemic Lupus Erythematosis	1.71 (1.46 to 2.01)
Inflammatory Bowel Disease	1.35 (1.26 to 1.45)
COPD	1.34 (1.29 to 1.40)
Asthma	1.23 (1.20 to 1.27)
Chronic Kidney Disease	1.16 (1.12 to 1.20)

Diabetes	1.04 (1.01 to 1.07)
Diabetes Type	
No diabetes	1
Type 1	1.33 (1.14 to 1.56)
Type 2	1.02 (0.99 to 1.05)
Unknown	1.15 (1.03 to 1.29)

OR, odds ratio. CI, confidence interval. *Adjusted for HIV, Leukaemia, Lymphoma, Myeloma, HSCT, Other Immune deficiencies, RA, SLE, IBD, COPD, Asthma, CKD, Depression, Diabetes, Smoking and Alcohol.

C: Different definition of exposure to oral corticosteroids and immunosuppressive conditions

Rationale

The definition of exposure to oral corticosteroids and other immunosuppressive therapy in the main analysis was derived from guidelines on zoster vaccine contraindications (a 14-day course of high-dose oral corticosteroids or other immunosuppressive therapies, within the month prior to index date). The vaccine contraindications suggest patients remain immunosuppressed for one month following the end of their prescription. However we acknowledge this definition may not capture all patients with immunosuppression due to these medications.

Our sensitivity analysis therefore defined exposure as anyone taking an oral corticosteroid or other immunosuppressant within 3 months prior to the index date, and placed no restrictions on duration or dose of prescription.

Results

A much higher number of patients were defined as exposed to immunosuppressive therapy using this broader criterion (table C1). The overall effect of oral corticosteroids and immunosuppressive therapies was slightly lower when using the 3-month definition compared to the vaccine contraindication definition, however the confidence intervals overlapped (table C1). There were no major differences in the effect of our main risk factors after adjusting for the broader definition of exposure to immunosuppressive drugs, compared to the main analyses (table C2).

Table C1: Relative risk of zoster in patients taking immunosuppressive therapy, defined as exposure in the previous 3 months.

	Cases n (%)	Controls n (%)	Unadjusted OR (99% CI)	Adjusted OR (99% CI)
Oral corticosteroid**	5304 (3.7)	12341 (2.3)	1.69 (1.62 to 1.77)	1.37 (1.31 to 1.44)
Other immunosuppressant drugs **	2361 (1.63)	4151 (0.76)	2.21 (2.07 to 2.36)	1.71 (1.57 to 1.86)

OR, odds ratio. CI, confidence interval. *Adjusted for HIV, Leukaemia, Lymphoma, Myeloma, HSCT, Other Immune deficiencies, Oral corticosteroids (previous 3 months), Other Immunosuppressive (previous 3 months), ICS, RA, SLE, IBD, COPD, Asthma, CKD, Depression, Diabetes, Smoking and Alcohol.
** Within 3 months prior to index date

Table C2: Relative risk of zoster in patients with various risk factors

	Adjusted OR (99% CI)*
Clinical conditions	
Rheumatoid Arthritis	1.17 (1.10 to 1.25)
Systemic Lupus Erythematosis	1.52 (1.27 to 1.82)
Inflammatory Bowel Disease	1.26 (1.17 to 1.37)
COPD	1.20 (1.14 to 1.26)
Asthma	1.11 (1.06 to 1.16)
Chronic Kidney Disease	1.11 (1.07 to 1.16)
Depression	1.15 (1.10 to 1.20)
Diabetes	1.01 (0.98 to 1.05)
Diabetes Type	
No diabetes	1
Type 1	1.25 (1.05 to 1.48)
Type 2	1.00 (0.97 to 1.03)
Unknown	1.11 (0.98 to 1.26)

OR, odds ratio. CI, confidence interval. *Adjusted for HIV, Leukaemia, Lymphoma, Myeloma, HSCT, Other Immune deficiencies, Oral corticosteroids (previous 3 months), Other Immunosuppressive (previous 3 months), ICS, RA, SLE, IBD, COPD, Asthma, CKD, Depression, Diabetes, Smoking and Alcohol.

D: Association of various risk factors with zoster, after additionally adjusting for patient-level socioeconomic status

Rationale

In the main analyses patients were matched on practice and thereby the analyses controlled for practice-level socioeconomic status. For patients registered at English practices and agreeing to their medical records being linked to other dataset, a patient level socioeconomic status score is available. Socioeconomic status (at the patient and practice level) is captured using quintiles of the Index of Multiple Deprivation score. At the patient level, the patient's home postcode is mapped at the lower level super output level to the corresponding 2007 IMD score; a low quintile represents the least deprived.

Results

In total, 427,689 (61.6%) patients had a patient-level socioeconomic status score. The results from our sensitivity analysis which additionally adjusts for patient-level socioeconomic status are shown in Table D1. There were no major differences compared to the main analyses.

Table D1: Relative risk of zoster in patients with various risk factors

	Adjusted OR (99% CI)*
Clinical conditions	
Rheumatoid Arthritis	1.54 (1.42 to 1.65)
Systemic Lupus Erythematosis	1.82 (1.46 to 2.27)
Inflammatory Bowel Disease	1.39 (1.26 to 1.54)
COPD	1.33 (1.26 to 1.40)
Asthma	1.21 (1.16 to 1.26)
Chronic Kidney Disease	1.13 (1.08 to 1.19)
Depression	1.16 (1.10 to 1.22)
Diabetes	1.01 (0.98 to 1.06)
Diabetes Type	
No diabetes	1
Type 1	1.30 (1.05 to 1.61)
Type 2	1.01 (0.96 to 1.05)
Unknown	1.09 (0.93 to 1.27)

OR, odds ratio. CI, confidence interval. *Adjusted for HIV, Leukaemia, Lymphoma, Myeloma, HSCT, Other Immune deficiencies, RA, SLE, IBD, COPD, Asthma, CKD, Depression, Diabetes, Smoking and Alcohol and patient-level SES.

E: Different definitions of active controls

Rationale

In the main analyses we only included "active" controls, by ensuring controls had at least one consultation anytime within an 18 month period around the index date. In these sensitivity analyses, we applied different definitions of "active" controls. First we ensured controls had a consultation anytime from 1 year prior, to 2 years following the index date. Second, we required controls to have a consultation in the three years prior to index date.

Results

In the first analysis, 12,891 controls and 35 cases were excluded (compared to 27,928 controls and 88 cases in the main analysis). This meant 145,012 cases of zoster and 564,373 controls were included. In the second sensitivity analysis (where controls were required to have contact 3 years prior to index date), 31,551 controls and 303 cases were excluded; this left 144,744 cases of zoster and 545,713 controls in the analysis. There were no differences in the study findings compared to the main analyses (Table E1).

Table E1: Relative risk of zoster in patients with various risk factors

	Adjusted OR (99% CI)*once excluding controls without contact anytime from 1 year prior, to 2 years following the index date	**Adjusted OR (99% CI)* once excluding controls without contact 3 years prior to index**
Clinical conditions		
Rheumatoid Arthritis	1.47 (1.39 to 1.56)	1.45 (1.37 to 1.54)
Systemic Lupus Erythematosis	1.72 (1.46 to 2.04)	1.70 (1.43 to 2.01)
Inflammatory Bowel Disease	1.37 (1.28 to 1.48)	1.35 (1.26 to 1.46)
COPD	1.33 (1.27 to 1.38)	1.31 (1.26 to 1.36)
Asthma	1.23 (1.20 to 1.28)	1.21 (1.17 to 1.25)
Chronic Kidney Disease	1.14 (1.10 to 1.19)	1.13 (1.09 to 1.07)

Unknown	1.15 (1.02 to 1.30)	1.13 (1.00 to 1.28)

OR, odds ratio. CI, confidence interval. *Adjusted for HIV, Leukaemia, Lymphoma, Myeloma, HSCT, Other Immune deficiencies, RA, SLE, IBD, COPD, Asthma, CKD, Depression, Diabetes, Smoking and Alcohol.

F: Consultation rate among patients with risk factors of interest

Rationale

We explored how frequently patients consulted the general practitioner as this may introduce ascertainment bias (i.e. patients visiting their general practitioner more frequently may be more likely to receive a zoster diagnosis). We calculated the mean yearly consultation rate prior to index date (by dividing the total number of face-to-face or telephone consultations during follow-up, by the total years of follow-up prior to index date) among patients with our risk factors of interest. We compared this to the mean consultation rate for epilepsy, to assess whether epilepsy patients had a similar likelihood of being diagnosed with zoster.

Results

The results are shown in Table F1. The consultation rates among patients with our risk factors of interest were very similar. The mean number of consultations per year among epilepsy patients was 10.2, suggesting these patients consult with similar frequency as patients with our risk factors of interest.

Table F1: Mean consultation rate prior to index date

	Mean number of consultations per year prior to index date
Clinical conditions	
Rheumatoid Arthritis	11.7
Systemic Lupus Erythematosis	10.9
Inflammatory Bowel Disease	9.7
COPD	11.7
Asthma	9.5
Chronic Kidney Disease	11.2
Depression	10.3
Diabetes	11.7

4.4. Additional methods: selecting controls

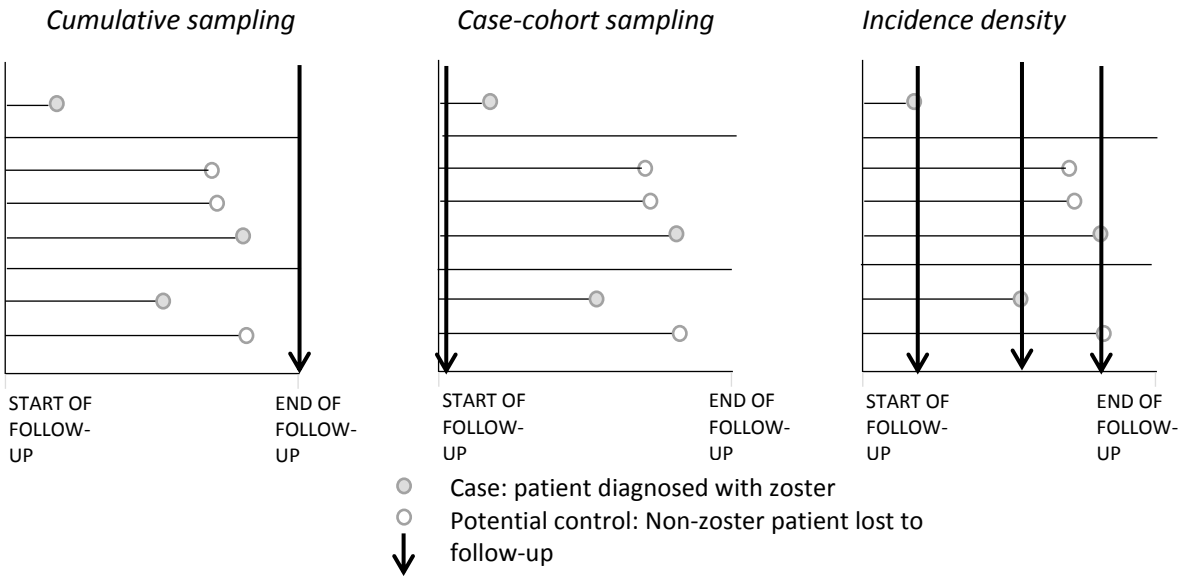
Appropriate control selection in case-control studies is key to generating valid results.

4.4.1. Sampling controls

There are three methods for sampling controls in case-control studies (represented pictorially in Figure 1).[128]

- *Cumulative sampling:* Traditionally employed by case-control studies, where non-cases are selected at the end of follow-up from "survivors" or those who are disease free.
- *Case-cohort sampling:* Where controls are selected from the entire cohort at baseline, in other words the base population. This method is also known as case-base sampling and is the least common method.
- *Incidence density sampling*: where controls are selected from the "risk set" of persons at risk at the time that each case occurs. Also called concurrent sampling.

Figure 1: Pictorial guide to the three different sampling methods used in case-control studies.



Note: the horizontal lines represents individual patients and their follow-up ends when the line stops.[129]

The matched case-control study in this chapter utilises incidence density sampling to match cases to controls; so for each case, controls were selected from all those "at risk" of zoster on the day the zoster case was diagnosed. It can be shown that when this method of control sampling is used, the resultant odds ratios (ORs) will estimate rate ratios for the outcome.[128,130]

Please note that although this method does provide rate ratio estimates, ORs were reported in the paper, as this is still technically correct and reporting rate ratios may have led to confusion.

In incidence density sampling, a single control could be matched to more than one case.[131] In other words, even after being selected as a control, individuals should remain eligible to be controls for other cases. Furthermore, cases can be controls prior to their zoster diagnosis.[131] These features ensure that the resulting OR will provide an unbiased estimate of the underlying rate ratio, by sampling controls from *all* those at risk of zoster at the time of sampling.

This sampling method was chosen as it is seen as the gold-standard sampling method for case-control studies and provides usefully interpretable effect estimates. The key disadvantages of *cumulative* sampling are: 1) cases cannot be in the control group, therefore the control group will not truly represent the entire base population at risk; and 2) by sampling controls at the end of follow-up, factors influencing loss to follow-up will influence the selection of controls. Finally, time-window bias, where the observation time during which exposures could have been recorded differs between cases and controls, is less of a problem if incidence density sampling is used.[132] By selecting controls from the all person-moments instead of the end of follow-up (as in cumulative sampling), the resulting exposure measurement for controls and cases are based on a more similar time span.

4.4.2. Matching cases and controls

Individual-level matching in case-control studies is the process of selecting a specified number of controls for each case, who are similar in terms of certain pre-specified characteristics, in order to reduce the confounding effects of those characteristics.[131] If the matching characteristic is a very strong confounder, then matching increases the efficiency of the study. Without matching, adjusting for these confounders could lead to multiple strata with few data. Forcing the cases and controls to have a similar distribution of the matching variables results in gains in precision and narrower confidence intervals (CIs).[133] Matching may also control for unmeasured confounders.

4.4.2.1. Matching factors

The matching factors were; age (within 1 year), gender and general practice. Calendar time is matched on by default when using incidence density sampling, as the controls have to be "active" (in this case, currently registered) when the case was diagnosed with zoster.

Age is a very strong risk factor for zoster, therefore an important confounder to control for as tightly as possible. Gender is another well-reported risk factor for zoster, and associated with a number of the potential risk factors. Matching on practice controlled for practice level SES helping to account for some unmeasured socioeconomic differences as well as allow heterogeneity between patterns of prescribing or recording to be accounted for.

4.4.2.2. Ratio of cases to controls

Cases were matched to up to four controls, as any more controls is not deemed to increase efficiency.[134]

4.4.3. Matching programme

With the help of a statistician, an algorithm was developed to individually match cases to controls, as follows:

1. All potential controls for each case were identified: as cases were eligible to be controls up until their zoster diagnosis, they were included in the pool of potential controls, with their end date redefined as their zoster date, minus one day.
2. Up to four controls were randomly selected for each case at random without replacement. Priority was given to potential controls closest in age to the case.

This produced matched sets; that is, one case and up to four controls.

4.5. Additional results: body mass index, smoking and alcohol status

BMI category, smoking status and alcohol use were investigated as potential confounders in the published zoster case-control study (section 4.2). As these factors were not pre-specified exposures of interest, their effect on zoster risk was not reported in the published paper. Table 7 below describes the relative risk of zoster by BMI, smoking and alcohol status. Please note BMI was not included in the fully adjusted models.

Table 7: Relative risk of zoster by BMI category, smoking status and alcohol use

	No (%)		OR (95% CI)		
	Cases (n=144959)	**Controls (n=549336)**	**Model 1***	**Model 2†**	**Model 3‡**
Risk factor					
BMI category					
Underweight	2,776 (2.1)	10,549 (2.2)	0.98 (0.92-1.04)	-	-
Normal weight	50,530 (38.6)	188,060 (38.7)	1.00	-	-
Overweight	47,886 (36.6)	177,603 (36.6)	1.00 (0.99-1.02)	-	-
Obese	29,581 (22.6)	109,440 (22.5)	1.01 (0.99-1.04)	-	-
Smoking					
Non-smoker	54,751 (38.2)	208,436 (38.8)	1.00	1.00	1.00
Current smoker	36,107 (25.2)	141,826 (26.4)	0.95 (0.93-0.97)	0.93 (0.91-0.95)	0.93 (0.91-0.95)
Ex-smoker	52,353 (36.6)	186,373 (34.7)	1.10 (1.08-1.12)	1.06 (1.04-1.08)	1.06 (1.04-1.09)
Alcohol use					
Non-drinker	14,481 (11.1)	56,774 (11.7)	1.00	1.00	1.00
Current drinker	103,113 (79.1)	383,976 (79.0)	1.05 (1.02-1.08)	1.05 (1.02-1.08)	1.05 (1.02-1.08)
Ex-drinker	12,786 (9.8)	45,242 (9.3)	1.13 (1.09-1.17)	1.11 (1.07-1.15)	1.11 (1.07-1.15)

*Adjusted for matching factors only.
†Adjusted for HIV, leukaemia, lymphoma, myeloma, haematopoietic stem cell transplantation, other unspecified cellular immune deficiencies, RA, SLE, IBD, COPD, asthma, CKD, depression, diabetes, smoking, and alcohol.
‡Additionally adjusted for oral corticosteroids, other immunosuppressive treatment, and ICS.

BMI: results and interpretation

There appeared to be no evidence that BMI category was associated with zoster risk, after adjusting for matching factors (age within one year, gender and practice). BMI category was therefore not included in the fully adjusted models (that is, model 2 and model 3 in table 7 above). This null association is in line with a previous Australian cohort study.[51]

Smoking: results and interpretation

From table 7 there is good evidence that current smokers have a small but significant reduction in the risk of zoster (Model 3: OR:0.93, 95%CI 0.91-0.95), compared to non-smokers. By contrast, ex-smokers have 1.06 times the odds of zoster than non-smokers (Model 3,

OR:1.06, 95%CI 1.04-1.09). These findings are in line with previous research, suggesting that current smoking may be protective against zoster and previous smoking may be a risk factor for zoster.[51,135]

Alcohol: results and interpretation

Being both a current and an ex-drinker was associated with 5% and 11% increased risk of zoster respectively. This is the first known study to report an association, albeit small, between alcohol use and zoster risk.

4.6. Additional biological evidence indicating impaired cell-mediated immunity associated with the exposures of interest

As described in the introduction, zoster reactivation occurs due to a waning of VZV-specific T cell-mediated immunity. Below is some biological evidence suggesting that the exposures of interest (specifically, RA, SLE, IBD, asthma, COPD, depression, diabetes, and CKD) investigated as risk factors for zoster in this thesis, are associated with impaired cell-mediated immune function.

4.6.1. Autoimmune conditions

Autoimmune conditions are associated with increased risk of infections,[136] indicating poor immune function. Cell-mediated immunity may be suppressed in patients with autoimmune conditions, due to the routine use of immunosuppressive medications, or the underlying disease itself.[136] RA patients have been shown to experience accelerated immune senescence of T cells and reduced T cell diversity.[137] A study of 38 SLE patients and 51 healthy controls, found decreased cellular immune responses and VZV-specific immunity in the SLE patients compared to healthy controls, and this was not influenced by immunosuppressive medication use.[138] This finding suggests that SLE, as a disease, may be driving impaired cell-mediated immune function. The other autoimmune condition assessed in this thesis is IBD. Little research exists exploring VZV-specific immunity among IBD patients, however IBD is reported to be associated with abnormalities in cell-mediated immunity.[58,139]

4.6.2. Asthma and chronic obstructive pulmonary disorder

Authors have suggested that asthma might play a role in waning cell-mediated immunity, as evidenced by reduced immune response to measles, mumps and rubella vaccination in asthmatic compared to non-asthmatic children.[140] It is currently unclear whether COPD as a disease itself alters cell-mediated immunity; however, some authors have suggested that COPD leads to systemic immune disturbances.[141] As asthma and COPD are both treated with corticosteroids, patients may experience drug-induced alterations in cell-mediated immunity from use of ICS[142-146] and oral corticosteroids.[104]

4.6.3. Depression

Depression may also lead to poorer cell-mediated immune function. Recent virology studies indirectly support the hypothesis that depression may lead to an increased risk of zoster. A

study demonstrated that 52 patients with major depressive disorder had lower VZV-specific cell-mediated immunity, compared to 52 age and sex-matched patients without depression, and the level of the immune response correlated negatively with the severity of depression.[147] Another study showed that depressed individuals had reduced VZV cell-mediated immune responses when administered the zoster vaccine.[148]

There is also evidence that stress, common in patients with depression, may also affect cell-mediated immunity. The central nervous, endocrine and immune system interact with each other, such that a dysregulation in one system can have an effect on the other systems. Stress can affect a number of neuroendocrine functions, including activating the hypothalamic–pituitary–adrenal axis which can thereby in turn affect cell-mediated immunity.[149,150] Additionally, patients experiencing stress are likely to have habits, such as reduced sleep, which may indirectly affect immune function. Virological evidence that astronauts have experienced sub-clinical VZV reactivation during space travel, suggests stress may trigger a reduced cell-meditated immune response.[151,152] Finally, evidence of a randomised controlled trial of a stress-reducing behavioural intervention, Tai Chi, found the Tai Chi group showed higher levels of VZV cell-mediated immunity than the control group (who received some health education) after 25 weeks.[153]

4.6.4. Chronic Kidney Disease

Researchers have suggested that a decline in renal function can result in reduced cell-mediated immunity. VZV-specific cell-mediated immunity has not been assessed in patients with kidney disease. However, patients with CKD demonstrate an increased susceptibility to infections (the second most common cause of death in dialysis patients is infection) and decreased serological response to vaccination, such as Hepatitis B and influenza, which points to an impaired cellular immune response.[154,155] There is also some evidence that CKD causes a diminished activation of T cells.[156] The causes of immune dysfunction in CKD are not fully understood, however uraemia (a raised level of waste products in the blood, usually eliminated by the kidneys), is thought to be the mediating factor.[157]

4.6.5. Diabetes

Patients with diabetes have more infections than patients without diabetes[158] and hyperglycaemia (too much blood sugar in the bloodstream) is believed to lead to immune suppression[159,160] and T-cell dysregulation.[161] Furthermore, a virological study found VZV-

specific cell-mediated immune responses were reduced in patients with diabetes, compared to healthy controls.[162]

4.7. Chapter summary

Quantification of risk factors for herpes zoster

- Current zoster vaccination campaigns focus on older people only.
- Recent literature has suggested that a range of clinical conditions are associated with an increased risk of zoster, raising the possibility that some younger people may be at high risk. However, large, highly powered studies investigating the association of these clinical conditions with zoster are lacking.
- A case-control study was carried out in CPRD with 144,959 zoster cases and 549,336 age, sex and practice-matched controls, and the associations between a range of potential risk factors and zoster were investigated.
- Conditions associated with increased risk of zoster included RA, SLE, IBD, COPD, asthma, CKD, type 1 diabetes and depression.
- The increased risks were generally greater among younger age groups.
- Those at highest risk of zoster remain those who have severely weakened immune systems and the current vaccine is contraindicated for these individuals. This emphasises that alternative strategies (which could include non-live vaccines and antiviral prophylaxis) are needed to reduce the risk of shingles among these patient groups.
- Further information about the risk of complications, particularly PHN, is needed to decide if it is cost-effective to vaccinate certain patients.

Chapter 5: Prescription of antiviral therapy after herpes zoster: who receives therapy?

5.1. Introduction

Antiviral medication is given to certain patients following zoster, to accelerate rash healing during an acute zoster episode and to limit the severity and duration of pain. Their effectiveness in preventing PHN is disputed. Understanding which patients receive antivirals in routine practice will be important to: 1) assess whether prescriptions guidelines are adhered to in UK general practice; and 2) inform the analysis in chapter 7, which evaluates the effect of antiviral use on the risk of PHN among zoster patients.

This research on the prescription of antiviral therapy following zoster was published in the British Journal of General Practice and is presented below. Please note at the time of publication, CPRD was called the General Practice Research Database.

Prescription of antiviral therapy after herpes zoster in general practice:

who receives therapy?

Abstract

Background
Antivirals can accelerate rash healing during an acute zoster episode and can limit the severity and duration of pain. Their use within 7 days of rash onset is recommended among specific patient groups.

Aim
To describe antiviral prescription patterns and patient characteristics associated with antiviral receipt after zoster diagnosis.

Design and setting
Descriptive study and risk factor analysis using electronic healthcare records from UK general practice.

Method
Incident adult zoster cases occurring between 2000 and 2011 were identified in the General Practice Research Database. Therapy records were searched for antiviral prescriptions of aciclovir, famciclovir, or valaciclovir within 7 days of zoster diagnosis. The proportion of incident zoster cases receiving antivirals was calculated and multivariable logistic regression used to assess associations between patient characteristics and antiviral use.

Results
Of 142 216 incident zoster cases 58.1% received an antiviral prescription. The majority (69.0%) were aciclovir. The proportion receiving antiviral prescriptions increased with age up to 65 years, then declined to 56.8% among patients aged ≥85 years. Being female and of higher socioeconomic status were associated with higher antiviral receipt. Antivirals were more commonly prescribed to immunosuppressed patients with herpes zoster (odds ratio 1.27; 95% CI = 1.22 to 1.33), however they were not given routinely to this patient group.

Conclusion
Antiviral therapies for zoster are under-prescribed in UK general practice even among groups, such as immunosuppressed and older individuals, for whom guidelines recommend treatment. Patients may present too late to receive treatment or physicians may decide that antivirals are not essential treatment. Consideration could be given to reviewing the guidelines.

Keywords
antivirals; database; epidemiology; general practice; GPRD; herpes zoster; shingles; United Kingdom.

INTRODUCTION

Herpes zoster presents as a painful unilateral vesicular dermatomal rash[1] resulting from reactivation of latent varicella zoster virus infection. Reactivation is thought to result from waning cell-mediated immunity. Zoster is common among older people with a lifetime risk of 10–30%, rising to 50% among those living to ≥85 years.[2] Post-herpetic neuralgia develops in around 20% of individuals aged ≥50 years[3] and causes persistent severe pain for months to years after rash onset.[4]

Antivirals have been demonstrated in multiple clinical trials to accelerate rash healing and limit the severity and duration of pain during an acute zoster episode.[4] There is also some evidence suggesting they may reduce the risk of post-herpetic neuralgia,[5–7] possibly by reducing neural damage which may contribute to its development.[4] Treatment options for post-herpetic neuralgia are limited, therefore the potential use of antivirals to prevent post-herpetic neuralgia is particularly important.

Current UK guidelines advise GPs to prescribe oral antiviral drugs within 72 hours of rash onset for: people aged ≥50 years, ophthalmic zoster, other non-truncal disease, immunosuppression, or individuals with moderate to severe pain or rash.[8] Guidelines further recommend treatment up to 1 week after rash onset, particularly when characteristics for severe zoster or complications are present, such as continued vesicle formation, older age, immunosuppression, or severe pain.[8]

Research on the proportion of zoster individuals prescribed antivirals is limited[3] and previous studies have reported overall use, rather than by specific risk groups. Zoster incidence is likely to increase in the UK, due to population ageing and increasing use of immunosuppressive therapies, and it is important to understand current prescribing patterns.

This study aims to analyse antiviral prescription patterns by patient characteristics after a zoster diagnosis in UK general practice.

METHOD

This is a descriptive and risk factor analysis of UK electronic healthcare records over a study period from 1 January 2000 to 13 June 2011.

Data source

This study utilised data from the UK General Practice Research Database (GPRD), a large computerised database of anonymised patient records that contains complete prescribing and diagnostic information in primary care and feedback from hospital referrals. It is one of the largest sources of continuous patient records in the UK, containing data on approximately 7% of the UK population and is broadly representative of patient and practice characteristics in the UK.

Selecting incident zoster cases

An incident zoster case was anyone aged ≥18 years with a diagnostic code for zoster

This is the full-length article (published online 26 Nov 2012) of an abridged version published in print. Cite this article as: **Br J Gen Pract 2012; DOI: 10.3399/bjgp12X659277**

How this fits in

This article is the first to describe who receives antiviral therapy following a zoster diagnosis within the UK. It highlights that antivirals are under-prescribed in UK primary care, including among those particularly recommended for treatment, such as older individuals and those with immunosuppressive conditions. Although patients may present too late to receive therapy, under-treatment may reflect poor adherence to treatment guidelines. Consideration could be given to reviewing the guidelines.

in GPRD during the study period, without any consultations for zoster during the previous year. For patients with recurrent zoster episodes during the study period only the first episode was included. Those with zoster episodes occurring within 1 year of the start date were excluded, to remove potentially incorrectly dated prevalent cases.[9] Patients diagnosed with zoster encephalitis, zoster meningitis, or with another central nervous system complication within 7 days of the first zoster record were also excluded (n = 113) as they would typically be treated in secondary care. Read Codes indicating the anatomical site of zoster were searched for in all records within a zoster episode, defined as 1 year following first zoster record. Site of zoster was categorised into ophthalmic, other non-truncal and unspecified site; there is no existing Read Code for truncal zoster.

Sociodemographic characteristics of zoster cases

Age, sex, and geographical health region were obtained from the extracted GPRD data. Age was categorised as 18–49, 50–64, 65–74, 75–84, or ≥85 years. Socioeconomic status was analysed using quintiles of the Index of Multiple Deprivation (IMD) score, available for patients registered at English practices agreeing to link medical records with other databases. The patient's home postcode is mapped at the lower level super output level to the corresponding 2007 IMD score; a low quintile represents the least deprived. As patient-level IMD score was not available for patients from unlinked practices in England, a sensitivity analysis was run using practice-level IMD quintile when patient-level IMD quintile was unavailable.[10]

Identifying comorbidities at zoster diagnosis

As NHS guidelines recommend antiviral prescription for all immunosuppressed individuals, prescribing patterns were explored in this group. Patients were considered severely immunosuppressed if they had a diagnosis within 2 years preceding their zoster episode of leukaemia, lymphoma, or a bone marrow transplant or if they had ever had a diagnosis of HIV, a splenectomy, an organ/tissue transplant, myeloma diagnosis, or 'other immune deficiencies' (for example, immunodeficiency with predominantly antibody defects such as selective IgA immune deficiency and agammaglobulinemia, aplastic anaemias, and non-specific diagnoses of immune disorder). Patients prescribed at least one immunosuppressive medication, including oral corticosteroids, ≤3 months before their zoster episode were also considered severely immunosuppressed.

To explore antiviral prescribing patterns among patients with moderate immunosuppression, the following autoimmune conditions were flagged: diabetes, rheumatoid arthritis, inflammatory bowel disease, and systemic lupus erythematosus.

Antiviral use

Antiviral prescriptions including aciclovir, famciclovir, or valaciclovir within 7 days of a zoster diagnosis were identified from GPRD therapy records.

Data analysis

Data were analysed using STATA/MP (version 11.2). The proportion of incident zoster cases receiving antivirals was determined, and described by various patient characteristics. The association between antiviral use and patient characteristics was assessed using multivariable logistic regression adjusting for age, sex, region, year, zoster site, and immunosuppression status. Socioeconomic status was not adjusted for as it was only available for selected English practices.

RESULTS

Between 2000 and 2011 142 216 incident zoster cases were identified. Of these 82 656 (58.1%) received an antiviral prescription within 7 days of diagnosis in GPRD. Of those prescribed antivirals 80 751 (97.7%) were given on the day of the zoster diagnosis. The most commonly prescribed antiviral was aciclovir (69.0%), followed by famciclovir (27.8%) and valaciclovir (3.5%). A small number (n = 224) of cases had two different antivirals prescribed on the same day and were included in both antiviral groups (therefore totals do not add up to 100%).

The proportion of patients prescribed antivirals increased with age up to

AV = antivirals. [a]Adjusted for age, sex, region, year, zoster site and immunosuppression status, based on severe immunosuppression. [b]Test for trend. [c]Analysis restricted to patients registered at English practices with IMD score available.

65–74 years, when the percentage plateaued and then reduced to 56.8% among patients aged ≥85 years (Table 1). Females were more likely to be prescribed antivirals compared to males (adjusted odds ratio [AOR] 1.11, 95% confidence interval [CI] = 1.09 to 1.13). However, the sex difference disappeared among patients aged ≥75 years (Figure 1) (in χ^2 tests $P>0.2$).

Patients with an ophthalmic zoster diagnosis were less likely to receive antivirals compared to patients with zoster at an unspecified site (AOR 0.66, 95% CI = 0.61 to 0.72) (Table 1). Similarly, patients with other non-truncal zoster were less likely to be prescribed antivirals (AOR 0.34, 95% CI = 0.30 to 0.40) (Table 1).

The percentage of patients receiving antivirals increased every year between 2000 and 2010, from 45.7% to 65.3% and this trend remained after adjusting for confounders (Table 1). Antiviral use varied by UK region. The lowest use of antivirals was in the north-east regions of England, specifically Yorkshire and Humber (51.9%) and the North East (52.8%). The highest use was in Northern Ireland (67.7%), where patients were 89% more likely to receive antivirals compared to patients in Yorkshire and Humber (AOR 1.89, 95% CI = 1.75 to 2.04). IMD score was available for 78 718/112 482 patients (70.0%) in England. The percentage of patients prescribed antivirals reduced with increasing IMD quintile, with 58.4% of patients in quintile zero and 54.6% in quintile four (most deprived) having received antiviral therapy (Table 1). Using practice-level IMD score for cases in England missing patient-level IMD, the results did not change (data not shown).

Zoster patients with immunosuppression were 27% more likely to receive antivirals compared to patients without immunosuppression (AOR 1.27, 95% CI = 1.22 to 1.33) (Table 2). Some evidence for greater antiviral use was found for all patients with severe immunosuppression, excluding myeloma (AOR 1.03, 95% CI = 0.85 to 1.24) (Table 2).

Of the selected autoimmune conditions considered to cause moderate immunosuppression, there was strong evidence that patients with rheumatoid arthritis were more likely to receive antiviral therapy, compared to patients without rheumatoid arthritis (Table 2). This effect was seen both among rheumatoid arthritis patients not taking immunosuppressive therapies (AOR 1.17, 95% CI = 1.05 to 1.29), and among rheumatoid arthritis patients on immunosuppressive therapy (AOR 1.28, 95% CI = 1.14 to 1.42). A similar pattern was seen among systemic lupus erythematosus patients (Table 2). Patients with inflammatory bowel disease were only more likely to receive therapy if they were on immunosuppressants (AOR 1.52, 95% CI

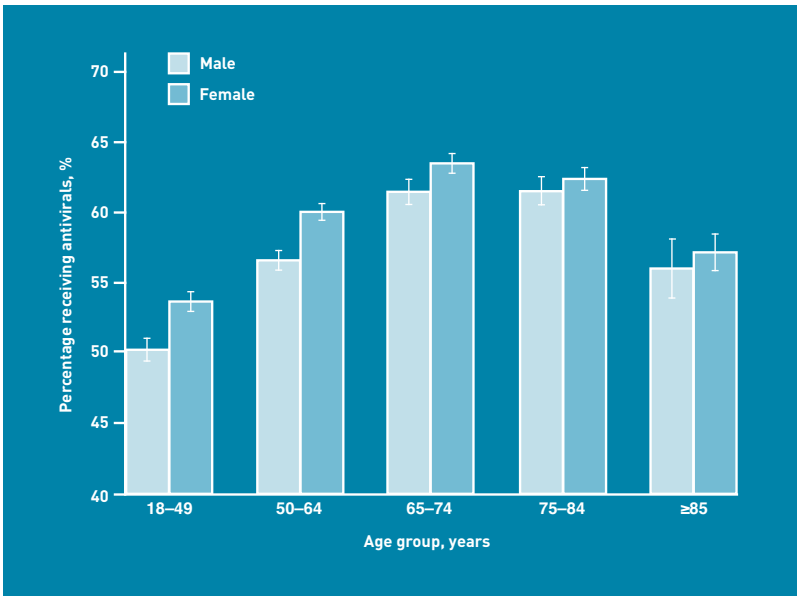

Figure 1. Percentage of patients receiving antiviral therapy, by age and sex (error bars represent 95% CIs).

= 1.24 to 1.85). Patients with diabetes were not more likely to be prescribed antivirals (Table 2).

DISCUSSION

Summary

In the UK between 2000 and 2011, the overall proportion of patients prescribed antivirals within 7 days of a zoster diagnosis was low (58.1%) though a clear increase was seen over time. Aciclovir was the most common antiviral prescribed. Antiviral prescriptions increased with age; however this trend stopped after age 65 years and prescriptions declined among patients ≥85 years. Being female, of higher socioeconomic status, and registered at a GP in Northern Ireland or Scotland was associated with higher antiviral receipt. Although antivirals were more commonly prescribed to immunosuppressed patients with herpes zoster, they were not given routinely in general practice to this patient group.

Why are antiviral prescriptions for zoster low? The finding that a low proportion of patients are prescribed antivirals for an acute episode of zoster correlates with a previous study of GPRD data reporting that 56.3% of 27 225 immunocompetent patients with herpes zoster aged ≥50 years received antivirals between 2000 and 2006.[3] These findings could suggest a lack of adherence to guidelines. Antivirals are generally safe, well tolerated,[4] and aciclovir is inexpensive, therefore neither adverse effects nor cost implications can explain their low use following zoster diagnosis. It is possible that antivirals are not seen as essential treatment, as they do not provide a cure, rather they can reduce duration of the rash and the severity of pain during the episode. Although antivirals are suggested to reduce the risk of post-herpetic neuralgia, evidence is inconclusive,[5–7] which may again deter physicians from prescribing them. This may be especially pertinent to mild cases of zoster.

An alternative explanation is patients are presenting too late to receive treatment; more than 72 hours after rash onset. This 72-hour cut-off reflects an arbitrary criterion used in clinical trials of antiviral therapy in patients with herpes zoster.[4] This may be an unrealistic time frame for patients to secure an appointment with their GP.[4] Therefore guidelines encourage GPs to 'consider' use of antivirals within 7 days of rash onset for older or immunosuppressed patients. The guidelines for treating patients presenting after 72 hours from rash onset lack clarity, and furthermore, are based on limited evidence[11–12] both of which may deter prescribing.

Patients may also present following the 7-day window when it is too late to receive antiviral therapy. Although data on time from actual rash onset to presentation to the GP is not available in this data set, two previous UK studies suggest patients present soon after rash onset: Scott *et al* reported that 50–60% of patients aged >50 years presented to GPs within 72 hours of rash onset,[13] and analyses of data from Thomas *et al* shows that 65% of adult patients with herpes zoster presented by 72 hours, with less than 7% presenting after 7 days.[14]

Additionally, a small proportion of immunosuppressed patients who get disseminated zoster will be referred, as per guidelines, to secondary care for systemic therapy and their antiviral use not recorded here. However this would not explain the low prescribing rates for the majority of patients in this study.

Why are there age, sex, regional, and socioeconomic differences? As expected the proportion of patients with herpes zoster prescribed antivirals increases with age. Explanations for why this trend plateaus at age 65 years and subsequently declines among the oldest may include; older patients being in nursing homes and presenting to GPs later, or reluctance to prescribe to older patients nearing the end of their life. Patients in Scotland and Northern Ireland were more often treated with antivirals, which may

Table 2. Proportion of patients prescribed antiviral medication, by comorbidities

Patient characteristic	*n*	% Treated	Unadjusted OR (95% CI)	Adjusted OR (95% CI)[a]	*P*-value

reflect patients accessing GP services more quickly or different prescribing cultures among physicians. Reasons why males and people of lower socioeconomic status were less likely to receive antivirals may include differences in when these groups access care or physicians differentially prescribing antivirals among these groups.

Antiviral use among patients with immunosuppression. It is recommended antivirals be given routinely to patients with immunosuppression; however the proportion receiving treatment ranged between 62–68%. This may again be explained by delay in consulting GPs, some patients with severe underlying comorbidities accessing antiviral therapy through secondary care or physicians not seeing antiviral treatment as a necessity.

Antiviral use by zoster site. Ophthalmic and other non-truncal zoster cases were less commonly prescribed antivirals than zoster cases where site was unspecified, even after adjusting for age, sex, region, year, and immunosuppression status. This is a surprising finding considering guidelines suggest these groups routinely be given antiviral therapy. Patients with Ramsay Hunt Syndrome, the most common other non-truncal diagnosis, may present initially without an obvious rash and delayed diagnosis might contribute to lower prescription rates in this group. Ophthalmic zoster patients may be immediately referred to secondary care for treatment, resulting in lower prescribing rates among this group. However, misclassification of zoster site is

likely as the zoster site was seldom recorded. Despite this, it is surprising that less than 50% of cases with a definite diagnosis of ophthalmic or other non-truncal zoster received antivirals.

Strengths and limitations

The GPRD is one of the largest databases of healthcare records and has excellent capture of primary care prescriptions. However, these data may not fully capture prescriptions in secondary care. A minority of patients, particularly those with severe underlying comorbidities, may obtain antiviral prescriptions in secondary or tertiary care. Therefore this study may underestimate the prescription of antivirals following an acute zoster episode. However, as these patients received a zoster diagnosis in primary care, it is likely that most would have received any subsequent antiviral prescription from their GP. Finally, there may be misclassification of immunosuppression status as newer biologic therapies are poorly recorded in GPRD and some patients on long-term immunosuppressive therapies may be given prescriptions 6-monthly and would not have been detected; it is unclear whether receipt of antivirals among such individuals would differ from that among those identified as immunosuppressed in this study.

Comparison with existing literature

Studies from the US, Italy, and Australia report higher proportions of patients with herpes zoster receiving antiviral prescriptions. A retrospective study of healthcare records in Italy between 2003 and 2005 found 78% of 3260 immunocompetent patients with herpes zoster aged ≥50 years received antivirals.[15] In Australia analysis of healthcare records between 2000–2006 showed that 73.5% of 379 incident zoster cases aged ≥50 years received antivirals[16] and a similarly high proportion was found in the US where 71.3% of 8741 newly diagnosed zoster adults (aged ≥19) received antivirals;[17] both studies included immunosuppressed and immunocompetent individuals. In contrast, data from a large database of general practice records in the Netherlands in 2001 found 22.5% of 1129 patients with herpes zoster aged ≥44 years received antivirals.[18] Observed variation in prescribing patterns between countries may reflect differences in healthcare systems or distribution of patients with characteristics more/less likely to get antivirals in study populations, or to variations in data quality.

Implications for research and practice

The proportion of patients in the UK receiving antivirals following a diagnosis of zoster in primary care is low. This research highlights the problem of under-prescribing of antivirals for zoster in UK general practice even for groups where clear guidelines recommend treatment.

Further research is required to understand the basis for the low proportions given antivirals. This is particularly pertinent for older and immunocompromised patients. Controlled trials assessing the benefits of antivirals prescribed >72 hours after rash onset would enable more detailed guidance for physicians and may increase antiviral prescribing if delay in presenting to GPs is a factor contributing to low antiviral use. Treatment guidelines could be reviewed to clarify which patients should be treated with antivirals when it is not possible to initiate treatment within 72 hours of rash onset.

5.3. Update of antiviral prescribing guidelines and literature:

The prescribing guidelines for use of antivirals during acute zoster have not changed since 2012, when the study was carried out and the paper published.

Regarding other literature on the use of antivirals during acute zoster in primary care, two relevant studies have been published since. Both studies are in accordance with previous literature, demonstrating that outside of the UK, a higher proportion of acute zoster patients receive antiviral prescriptions. A study within a large general practice in New Zealand between 2004 and 2009, found that of 278 incident zoster patients (≥18 years), 82% received antiviral treatment; treatment was higher among ophthalmic zoster patients (97% received antivirals) and patients presenting within 3 days of symptom onset (96%).[163] Another prospective study within 108 general practices in Italy between 2009 and 2010, found higher use of antivirals in immunocompetent patients aged ≥50 years;[164] of 413 patients, 91.5% of patients received antivirals and treatment was initiated a median of 2 days after rash onset.

5.4. Chapter summary

Antiviral use following first episode of zoster

- This chapter describes who receives antiviral therapy following a zoster diagnosis within the UK.
- A descriptive study was carried out in CPRD among 142,216 zoster patients to calculate the proportion receiving antivirals within seven days of zoster diagnosis.
- Antivirals are under-prescribed in UK primary care; 58.1% of zoster cases received an antiviral prescription within seven days of diagnosis. Even in those where guidelines recommend the use of antivirals, specifically older individuals and those with immunosuppressive conditions, treatment was not always received.
- Although patients may present too late to receive therapy, under-treatment may reflect poor adherence to treatment guidelines.
- Consideration could be given to reviewing the guidelines.

Chapter 6: Systematic review and meta-analysis of risk factors for postherpetic neuralgia

6.1. Introduction

As well as exploring risk factors for zoster, this thesis aimed to explore risk factors for PHN. Prior to conducting an original research study in CPRD, a systematic review and meta-analysis was carried out collating and presenting evidence regarding risk factors for PHN within zoster patients.

The article, published in the journal Pain, is presented below. This is followed up with the article's appendices, containing work and details that were too extensive for the main paper, specifically: further data extraction details, risk of bias assessment details and letters to authors (requesting further study details).

Following the paper and its appendices, there is an additional, shorter review of articles investigating risk factors for PHN within general population samples. The published review only included articles set within cohorts of zoster patients. In terms of vaccination policy, it is also informative to know who, within the general population, is at high risk of PHN, because such individuals could potentially be targeted for vaccination before developing zoster, therefore it was considered important to summarise this literature.

A systematic review and meta-analysis of risk factors for postherpetic neuralgia

Harriet J. Forbes*, Sara L. Thomas, Liam Smeeth, Tim Clayton, Ruth Farmer, Krishnan Bhaskaran, Sinéad M. Langan

Abstract

Patients with herpes zoster can develop persistent pain after rash healing, a complication known as postherpetic neuralgia. By preventing zoster through vaccination, the risk of this common complication is reduced. We searched MEDLINE and Embase for studies assessing risk factors for postherpetic neuralgia, with a view to informing vaccination policy. Nineteen prospective studies were identified. Meta-analysis showed significant increases in the risk of postherpetic neuralgia with clinical features of acute zoster including prodromal pain (summary rate ratio 2.29, 95% confidence interval: 1.42-3.69), severe acute pain (2.23, 1.71-2.92), severe rash (2.63, 1.89-3.66), and ophthalmic involvement (2.51, 1.29-4.86). Older age was significantly associated with postherpetic neuralgia; for individual studies, relative risk estimates per 10-year increase ranged from 1.22 to 3.11. Evidence for differences by gender was conflicting, with considerable between-study heterogeneity. A proportion of studies reported an increased risk of postherpetic neuralgia with severe immunosuppression (studies, n = 3/5) and diabetes mellitus (n = 1/4). Systemic lupus erythematosus, recent trauma, and personality disorder symptoms were associated with postherpetic neuralgia in single studies. No evidence of higher postherpetic neuralgia risk was found with depression (n = 4) or cancer (n = 5). Our review confirms a number of clinical features of acute zoster are risk factors for postherpetic neuralgia. It has also identified a range of possible vaccine-targetable risk factors for postherpetic neuralgia; yet aside from age-associated risks, evidence regarding risk factors to inform zoster vaccination policy is currently limited.

Keywords: Herpes zoster, Postherpetic neuralgia, Epidemiology, Risk factors

1. Introduction

Postherpetic neuralgia (PHN) is pain after an acute episode of herpes zoster (commonly known as shingles) continuing beyond rash healing.[16] The pain has been described as a constant burning or stabbing sensation, and some individuals experience allodynia (pain triggered from light contact with nonpainful stimuli).[47] Symptoms can persist for months or even years, and the condition can profoundly affect a patient's quality of life.[12,24] PHN is the most common complication of zoster; an estimated 12.5% of patients with zoster aged ≥50 years have PHN 3 months after zoster onset, and the proportion affected increases sharply with age.

Postherpetic neuralgia is often refractory to treatment.[10,20,40] Despite decades of research, evidence for the efficacy of administering antivirals at first appearance of the rash in reducing PHN incidence is unconvincing.[7] However, an effective live-attenuated vaccine is now available providing protection against zoster and might be used to protect those most likely to develop PHN and other complications of zoster.[30,36] Apart from age, other often reported risk factors for PHN relate largely to characteristics of the acute zoster episode, particularly, the severity of acute pain and rash at initial zoster presentation; however, the evidence has not been systematically reviewed.[14,31,32,42,48] Furthermore, as these are not vaccine-targetable, there is interest in identifying risk factors for PHN, which can be identified before the zoster episode, to inform zoster vaccination policy.

This article aims to systematically collate and summarise the epidemiological literature on risk factors for PHN including clinical features of acute zoster and those which are "vaccine-targetable."

2. Methods

2.1. Study selection

2.1.1. Search terms

We searched all published journal articles in MEDLINE and Embase between 1950 and February 3, 2014. We searched for articles containing PHN terms and risk factor analysis terms (Box 1 for full details). The search strategy used both subject heading and text word searches. Initial search terms were updated after searching the reference lists of relevant articles. To capture relevant grey literature, the New York Academy of Medicine Grey Literature Report (www.greylit.org), the Electronic Theses Online Service through the British Library (http://ethos.bl.uk), and the ISI Conference Proceedings Citation Index

Sponsorships or competing interests that may be relevant to content are disclosed at the end of this article.

K. Bhaskaran and S. M. Langan contributed equally to the article.

2.2. Inclusion and exclusion criteria

Criteria were developed in an iterative process after preliminary searches. We included studies based on original data from analytical epidemiological studies, among adults (18 years+) with zoster. Postherpetic neuralgia had to be a study outcome and an age-adjusted effect estimate was required. We included risk factors, which were either (1) clinical features of the acute zoster episode or (2) vaccine-targetable, defined as risk factors identifiable before the onset of the zoster rash. Studies assessing only age as a risk factor were required to treat age as a continuous exposure (ie, linear on a log scale) such that its effects on PHN risk could be reported per 10-year increase. Studies assessing genes as risk factors for PHN were not required to have an age-adjusted effect measure, because allele frequencies are not typically associated with age.

We omitted studies assessing antiviral therapy as a determinant of PHN as they have been recently summarised in a Cochrane Systematic Review[7]; we also omitted studies assessing other PHN treatments (such as acupuncture and corticosteroids). We excluded studies examining risk factors for PHN within a general population sample (where patients with PHN were compared with non-zoster controls) because the risk of PHN in the general population comprises 2 parts; first, the risk of zoster and second, the risk of developing PHN among those with zoster. In these studies, it is impossible to disentangle whether any identified risk factors are simply predictive of zoster itself, or whether they are specifically risk factors for getting PHN. We also excluded studies restricted to specific clinical subgroups of patients with zoster, such as individuals with HIV, because their risk factors for PHN may differ. We restricted to English articles only; however, we did not place any restriction on study location or publication status.

2.3. Selecting studies

The titles and abstracts of all identified articles were assessed. If a study was deemed to potentially fulfil the inclusion criteria, full-text versions were retrieved and assessed. Reference lists of all retrieved articles were searched. To assess how reliably the study eligibility criteria were applied, a second author (R.F.) applied the inclusion criteria to a random 10% sample of all articles, and agreement between the primary allocation and the sample allocation was tested using Cohen's kappa statistic.[29] A kappa score of 1 denotes full agreement, and kappa values greater than 0.75 indicate excellent agreement.[44]

2.4. Data extraction

Extraction tables were piloted by S. L. Thomas and H. J. Forbes and then applied to remaining studies. Data (listed in Appendix, available online as Supplemental Digital Content at http://links.lww.com/PAIN/A132) were extracted by H. J. Forbes for each study. Authors were contacted for missing information (see appendix for template e-mail to corresponding authors, available online as Supplemental Digital Content at http://links.lww.com/PAIN/A132). When individual studies used multiple definitions of PHN, results classifying PHN as pain at 3 months after zoster onset (or that closest to 3 months) were extracted for the main analysis, as this is the most widely used definition of PHN.[12,17,30,36,45] Results from other PHN definitions were extracted for the Appendix (available online as Supplemental Digital Content at http://links.lww.com/PAIN/A132).

2.5. Assessing risk of bias

The risk of bias assessment was based on the Cochrane Collaboration approach,[1] in which each study is assessed separately for prespecified bias domains (see Appendix for further details available online as Supplemental Digital Content at http://links.lww.com/PAIN/A132).

We also considered the validity of each study based on the sampling of patients with zoster, numbers declining to participate, and their characteristics, particularly the percentage developing PHN.

2.6. Data analysis

When at least 2 studies were deemed to be capturing the same risk factor within similar populations, we assessed between-study heterogeneity using the Cochrane Q statistic and the I^2 statistic, with $I^2 > 50\%$ used as a threshold indicating moderate heterogeneity. In the absence of heterogeneity, we planned to combine the estimates and produce a summary relative risk using fixed effects meta-analysis. However, for some risk factors, there was significant between-study statistical heterogeneity; therefore, we performed posthoc analysis to help ascertain the possible reasons for heterogeneity. This included rerunning the meta-analysis removing studies at high risk of bias and comparing I^2 values between clinical and methodological subgroups to evaluate potential sources of heterogeneity.[22] For this latter analysis, summary estimates from subgroups were formally compared using meta-regression; we compared subgroups according to (1) mean age of the study population (≥60 years vs <60 years), (2) definition of PHN (pain at 4 months vs pain at 3 months), (3) ascertainment of PHN (self-reported vs ascertained from medical records), (4) whether immunosuppressive patients were included or excluded, and (5) sources of study population (primary care vs other).

We also created a funnel plot to determine the risk of publication bias; gender was the only risk factor assessed in sufficient studies to be suitable for assessment (age effects were reported in different units making it unsuitable). The odds ratios (OR), representing the effect estimate of gender on PHN, were plotted against the standard error of the log odds,[41] representing the precision of the estimate, and symmetry was assessed visually (as there were too few studies to perform a formal test).[43] Statistical analyses were performed in STATA (version 13.1).

3. Results

The initial search identified 3614 articles. After removing duplicates, 2559 titles and abstracts were screened. Of these, 116 full-text articles were retrieved, 19 of which were included in the review (**Fig. 1**). Excluded studies are listed in the Appendix (Table A1), available online as Supplemental Digital Content at http://links.lww.com/PAIN/A132.

Agreement between reviewers over the application of the inclusion criteria was very good (kappa score, 0.88). From the 10% sample of articles double screened, 1 study was not agreed on; the second reviewer initially selected this study[11] for inclusion; however, both reviewers subsequently agreed this extra article replicated a study already selected.[13]

3.1. Study characteristics and findings

Study characteristics are described in **Table 1**. There were 18 cohort studies and 1 case-base study (a modified case–control study, where the risk ratio is estimated by sampling controls from those at risk at the start of follow-up).[39] Study sizes ranged from 55 to 34,280, and 17/19 studies had less than 1000 participants at baseline. Zoster diagnoses were predominantly based on clinical opinion. Definitions of PHN were presence of pain 3 months after rash onset in 10 studies, although other definitions from 1 to 6 months were used. The percentage of patients with zoster developing PHN ranged from 2.6% to 67.3%. Mean age of study participants (available in 9 studies) ranged from 52.3 to 67.7 years. Studies were all from high-income countries.

Study findings are summarised in **Table 2** and **Figures 2 and 3**. Data were collected on clinical features of the acute episode including pain (15), rash extent and location (14), rash duration (9), sensory dysfunction (3), and other clinical features (11), and also vaccine-targetable risk factors including age and gender (18 studies), severe immunosuppression (5), other physical comorbidities such as autoimmune conditions (4), diabetes (6), cancer (5), recent physical trauma (1), psychological comorbidities (4), and other risk factors (9).

3.2. Clinical features of acute zoster episode as risk factors

3.2.1. Pain

3.2.1.1. Prodrome

Eleven cohort studies and the case-base study collected data on prodromal pain, ie, pain appearing before rash onset. Seven included prodromal pain in the final age-adjusted model and 5 reported effect estimates, with each giving a point estimate above 1. We obtained a pooled effect estimate of 2.29, 95% confidence interval (CI): 1.42 to 3.69 ($P_{heterogeneity} = 0.716$; $I^2 = 0.0\%$) in fixed effect meta-analysis. A cohort study among 533 immunocompetent patients reported a shorter prodrome (≤3 days) before rash onset was associated with reduced risk of PHN (adjOR: 0.49, 95% CI: 0.24-0.99).

3.2.1.2. Severe acute pain during zoster

Twelve cohort studies investigated severe acute pain as a risk factor for PHN. Although definitions of severe acute pain varied among studies, eg, pain scoring ≥4 using the Neuropathic Pain Questionnaire[5] and pain scoring ≥5 on the Visual Analogue Scale,[9] 8 reported it as a binary variable enabling us to pool estimates; there was good evidence that severe acute pain was associated with increased risk of PHN (rate ratio [RR]: 2.23, 95% CI: 1.71-2.92, $P_{heterogeneity} = 0.649$; $I^2 = 0.0\%$).

3.2.1.3. Allodynia

Allodynia was investigated in 3 cohort studies. One study reported a greater than 4-fold increased risk of PHN with brush (adjOR: 5.89, 95% CI: 1.50-23.1) and stretch-evoked allodynia (adjOR: 4.13, 95% CI: 0.98-17.50)[19]; however, small numbers (N = 93) led to wide CIs. A study among hospital patients treated in a pain clinic found no effect of allodynia (definition unclear; adjOR: 0.82, 95% CI: 0.24-2.81), whereas a final cohort study similarly reported no evidence of effect.[5,26] A summary estimate was not calculated because of the varying definitions of allodynia.

3.2.1.4. Pain interferes with daily functioning

Pain interfering with daily functioning at zoster onset was assessed in 3 cohort studies. The first, among 1358 individuals, reported a 1-unit increase in zoster brief pain inventory interference score was associated with 18% increase in PHN risk (adjOR: 1.18, 95% CI: 1.05-1.31).[13] Two other cohort studies reported binary (yes or

[1] *The Cochrane Collaboration have tools for assessing bias in randomized trials (Higgins JP, Altman DG, Gotzsche PC, et al. The Cochrane Collaboration's tool for assessing risk of bias in randomised trials. BMJ 2011: 343: d5928) and non-randomised studies (Sterne JAC HJ, Reeves BC. On behalf of the development group for ACROBAT-NRSI. A Cochrane risk of bias assessment tool: for non-randomized studies of interventions (ACROBAT-NRSI). 2014 Available from: www.riskofbias.info.). Both tools pre-specify bias domains, within which there may be more than one item. Each item is assigned a judgment of risk along with a supporting comment for the judgement.*

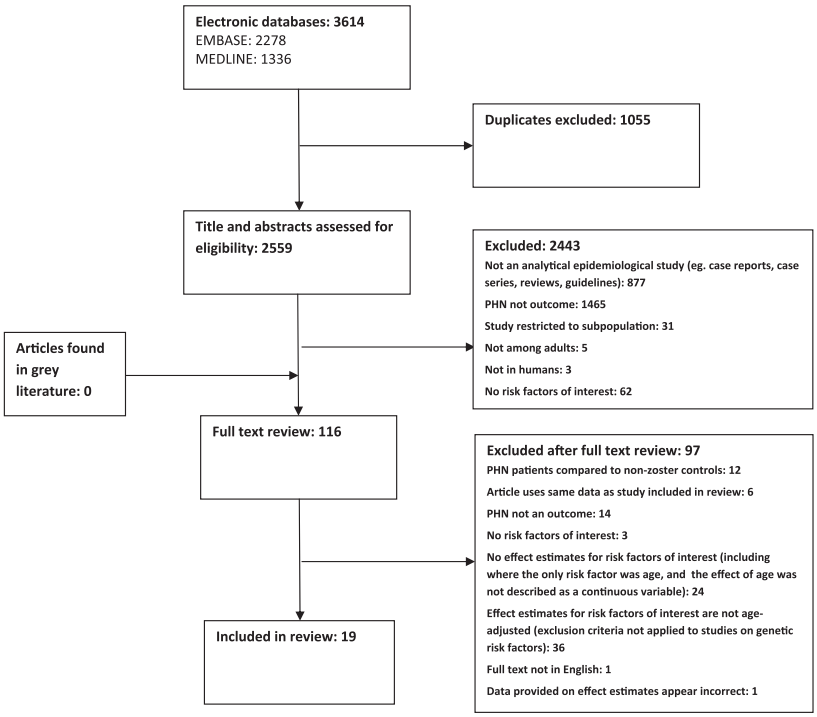

Figure 1. Flow diagram describing study selection.

no) data on pain interference. One found over 2-fold increased risk,[27] whereas the other found no evidence of association; the summary estimate of these 2 studies suggested there was strong evidence that pain interfering with daily functioning was associated with PHN (summary RR: 2.10, 95% CI: 1.27-3.48).

3.2.2. Rash severity and location

3.2.2.1. Severe rash

Rash severity data were collected in 8 studies. Five included it in their final age-adjusted model (although one did not report an OR); when combined in meta-analysis, severe rash was strongly associated with PHN risk (summary RR: 2.63, 95% CI: 1.89-3.66, $P_{heterogeneity} = 0.892$; $I^2 = 0.0\%$).

3.2.2.2. Ophthalmic involvement

A total of 13 studies recorded information on zoster location. Only 3 studies reported an effect estimate for ophthalmic involvement. Each of these 3 studies reported a point estimate above 1, yet the CIs crossed 1. When combining in a meta-analysis, there was evidence that ophthalmic zoster was associated with over twice the risk of PHN, compared with nonophthalmic zoster (summary RR: 2.51, 95% CI: 1.29-4.86, $P_{heterogeneity} = 0.782$; $I^2 = 0.0\%$).

3.2.3. Rash duration at presentation

Longer rash duration at presentation of zoster showed some evidence of being associated with reduced risk of PHN. A study on 598 immunocompetent patients showed for everyday the rash was present since presentation in primary care; there was over 20% reduced risk of PHN (adjOR: 0.78, 95% CI: 0.64-0.97).[35] Three other cohort studies estimated the risk of PHN for everyday from onset to diagnosis; point estimates were all below 1 (yet CIs were wide).[9,25,27] The summary estimate from meta-analysis showed a small reduction in PHN risk with everyday since rash onset (0.93, 95% CI: 0.86-0.99).

3.2.4. Other

One study assessed pinprick hypaesthesia (or numbness) as a risk factor for PHN: it was associated with a 7-fold increased risk of PHN (adjOR: 7.72, 95% CI: 2.00-29.90).

3.3. Vaccine-targetable risk factors

3.3.1. Age

Eighteen studies assessing the effects of age showed an increased risk of PHN with greater age. When possible, we summarised the effect of a 10-year increase in age on PHN risk (n = 9). The point estimates ranged from 1.22 to 3.11 per 10 years; the meta-analysis showed strong evidence of between-study heterogeneity ($P_{heterogeneity} = 0.029$; $I^2 = 55.1\%$). A small study (N = 249) showing an increased risk of PHN with a 10-year increase in age (adjRR: 1.22, 95% CI: 1.00-1.48) was excluded from the meta-analysis as the effect was reported as a risk ratio. In posthoc analysis, there was some weak evidence that the effect of age was associated with age of the study population (*P* value from meta-regression = 0.08; specifically the effect of age on PHN risk seemed higher in studies where the mean age was ≥60

Table 1

Studies assessing vaccine-targetable risk factors for postherpetic neuralgia nested within a population of patients with zoster: study characteristics.

Cohort studies

First author publication year	Country, year of study	Study population	Study size	Mean (SD) age in years at baseline	Outcome	Patients with PHN, n (%)	Definition and method of identifying zoster	Definition and method of ascertaining PHN	Method of ascertaining risk factor(s)	Risk factors assessed	Statistical analysis
Asada et al.[2]	Japan, 2008-2010	Patients with acute zoster registered in a cohort study on VZV immunity; aged ≥50 y	258 recruited 247 analysed 11 lost to follow-up	Not reported	PHN at 3 mo after zoster	32 (13.0)	Notified during telephone follow-up and confirmed through evaluation of clinical symptoms by 3 dermatologists and PCR	Pain 3 mo after rash onset Telephone survey to ascertain pain status by secretariat members.	Survey forms and examination by dermatologists	Age, gender, history of zoster, state of VZV-specific cell-mediated immunity (using VZV skin test reaction: no oedema formation and <5 mm diameter of red skin indicated weaker VZV-specific cell-mediated immunity)	Logistic regression
Bouhassira et al.[5]	France, 2007-2008	Patients presenting to General Practitioners (GPs) years with acute zoster; aged ≥50 y	1358 recruited 1091 analysed 267 lost to follow-up	67.7 (10.7)	PHN at 3 mo after zoster	127 (11.6)	Physician diagnosis within 7 d of rash onset, no history of zoster within previous 12 mo	Pain 3 mo after rash onset Telephone interview, using question, "Do you still have pain associated with your shingles?"	Physician interview and patient completed questionnaire at zoster diagnosis	Age, gender, family situation, living arrangements, delay in diagnosis, associated disease (undefined), average pain intensity, pressure allodynia, brush-evoked allodynia, global DN4 score, NPSI score, ZBPI interference score, SF-12 physical and mental component score, HADS score, and analgesic treatment	Logistic regression
Cebrián-Cuenca et al.[6]	Spain, 2006-07	Convenience sample of patients with acute zoster from 25 general practitioners; aged >14 y	146 recruited 124 analysed 22 lost to follow-up 16 declined to participate	Median 63.5 (range: 19-94)*	PHN at 3 mo after zoster	18 (14.5)	Physician diagnosis of zoster	Pain 3 mo after rash onset. Telephone/home interview by study investigators	Interview with patients and review of medical records	Age, gender, prodromal pain, extremities localization, sacrum localization, time between symptom onset and clinical diagnosis, time between rash onset and clinical diagnosis, antiviral use	Logistic regression
Coen et al.[9]	England, 1998-2001	Patients presenting to primary care with acute zoster; any age	280 recruited 272 analysed 8 lost to follow-up	Not reported (range 0-99)	PHN at 3 mo after zoster	52/250 (20.8)	Physician diagnosis within 7 d of rash, referred to 2 investigators for clinical and PCR or IFA confirmation	VAS score ≥3.3 mo after rash onset Follow-up visit or telephone interview with research nurse	Physician interview at enrolment	Age, gender, prodromal pain, extent of rash, time from onset of rash, ophthalmic branch involvement, pain severity using VAS	Logistic regression

APOE, alipoprotein E; C^, sixth cervical dermatome; DN4, neuropathic pain questionnaire with 4 questions; EQ-5D: questionnaire on zoster pain and health-related quality of life; EHR, electronic health care record; HADS, hospital anxiety and depression scale; HCV, hepatitis C virus; HMO, health maintenance organisation; *ICD-9*, International Classification of Diseases version 9; IFA, immunofluorescence of antigen; NPSI, neuropathic pain symptom inventory score; NSAIDS, Nonsteroidal antiinflammatory drugs; PCR, polymerase chain reaction; SF-12, short-form 12; VAS, visual analogue scale ranging from 0 (no pain) to 100 (worst pain ever experienced); VZV, varicella zoster virus; ZBPI, zoster brief pain inventory interference score.

years) (Appendix Table A2, available online as Supplemental Digital Content at http://links.lww.com/PAIN/A132). There was no evidence that the effect of age on PHN risk varied by definition of PHN ($P = 0.52$), ascertainment of PHN ($P = 0.14$), immunosuppression status ($P = 0.23$), or sources of study population ($P = 0.18$).

3.3.2. Gender

Of 9 studies reporting the age-adjusted association between gender and PHN, some suggested an increased risk of PHN among females,[9,25,38] others a decreased risk,[2,5] whereas others found no evidence of an association.[2,6,8,23,33,37] These conflicting results were supported by strong evidence of between-study heterogeneity ($P_{heterogeneity} < 0.001$; $I^2 = 73.9\%$). In posthoc analysis, the effect of female gender seemed protective in studies in which the mean age was ≥60 years, compared with among studies with mean age <60 years, for which female gender increased the risk of PHN; heterogeneity was reduced within these subgroups (<1% in both) (Appendix Table A2, available online as Supplemental Digital Content at http://links.lww.com/PAIN/A132). There was no evidence that the effect of gender on PHN risk varied by definition of PHN ($P = 0.45$), ascertainment of PHN ($P = 0.83$), immunosuppression status ($P = 0.25$), or sources of study population ($P = 0.97$). These analyses were limited by 4/7 studies in meta-analysis of gender having at least 1 bias domain assigned high-risk.

3.3.3. Severe immunosuppression

A cohort study among patients with zoster≥18 years found immunosuppression (including HIV, currently treated for cancer, or exposed to high-dose corticosteroids) was more common in patients with PHN (15%, n = 3/20) than without (7.3%, n = 6/82); but the sample size was too small to be conclusive.[27] Another cohort study among patients ≥50 years of age reintroduced 12 patients with immunosuppression excluded from the main analysis (defined as using high-dose oral corticosteroids/other immunosuppressive drugs, having invasive cancer or HIV/AIDS); these patients had an increased risk of PHN after adjustment for confounders (adjRR: 1.98, 95% CI: 1.14-3.45).[13] Finally, the case-base study in the United States found connective tissue disease, HIV, or organ allograft was associated with 10-fold increased risk of PHN, although the CI was wide (adjOR: 9.5, 95% CI: 2.0-45.0).[8] Two studies specifically assessed HIV: one excluded HIV from the final multivariable analyses,[38] whereas another found over 50% decreased risk of PHN among patients with HIV (antiretroviral treatment status not reported) (adjRR: 0.48, 95% CI: 0.26-0.86).[23] The latter study also reported strong evidence of an increased risk of PHN with lymphoma/leukaemia (adjRR: 1.74, 95% CI: 1.32-2.28).

3.3.4. Other physical comorbidities

3.3.4.1. Overall physical health

One study measured overall health status at zoster presentation using the physical component summary score and found a decreased risk of PHN with better physical health.[5] The second study summed total number of reported medical conditions and found no evidence of association with PHN.[27]

3.3.4.2. Autoimmune conditions

A large cohort study among 34,280 patients with zoster identified in Taiwanese electronic health insurance records identified 284 patients with systemic lupus erythematosus (0.83%), who were

Table 2

Association between PHN and various risk factors (defined as either vaccine-targetable or clinical features of the acute zoster episode): risk factors, adjusted effect measure and 95% confidence interval (CI) by study.

‡ Physical Health measured using the Life Stressors and Social Resources Inventory, which sums the total number of patient reported medical conditions.
§composite score ranges from 0-100 numerical pain ratings and McGill Pain Questionaire Present Pain Intensity ratings of average and worst shingles pain.
‖ Adjusted for age (continuous variable), presence (yes or no) of prodromal symptoms, severe pain, or comorbid conditions; and number of health care encounters.
APOE, alipoprotein E; DN4, Neuropathic pain questionnaire with 4 questions; EQ-5D, questionnaire on zoster pain and health-related quality of life; HCV, Hepatitis C virus; NPSI, neuropathic pain symptom inventory score; RR, rate ratio; SF-12, short-form 12; SLE, systemic lupus erythematosus; VAS, visual analogue scale, ranging from 0 (nonpain) to 100 (worst pain ever experienced); VZV, varicella zoster virus; y, year; ZBPI, zoster brief pain inventory interference score.
¶ PCS, physical component summary score, MCS, mental component summary score (a patient reported survey of physical/mental health using short form 12 (SF-12); score <50 represented below-average health status).
#Study used ordered logistic regression, therefore the parameters represent the exposure ORs for being the highest outcome categories, compared with the lowest outcome categories: it is assumed the effect of exposure is the same for all splits of the outcome categories.

more than twice as likely to develop PHN (adjRR: 2.27, 95% CI: 1.75-2.94).[23] Another smaller study (N = 837) using electronic medical records from the Netherlands collected data on lupus and rheumatoid arthritis; however, they were not included in the final model (numbers not reported).[33]

3.3.4.3. Diabetes

Three cohort studies reported point estimates for the association between diabetes and PHN ≥1 in multivariable analyses; however, there was insufficient evidence to confirm an association.[8,26,33] A larger cohort study among 34,280 patients with zoster did find evidence of an increased risk (adjRR: 1.35, 95% CI: 1.25-1.47).[23] There was no evidence of between-study heterogeneity for studies reporting age-adjusted diabetes effects ($P_{heterogeneity}$ = 0.564; I^2 = 0.0%); the pooled effect estimate was 1.36 (95% CI: 1.25-1.47) in the fixed effect meta-analysis; however, the large study (N = 34,280) dominated the pooled relative risk (contributing 99.1% to the model).

3.3.4.4. Cancer

Five studies investigated cancer and its relationship with PHN; 3 excluded it from the final model.[26,28,38] Breast and liver cancer were investigated in a single study, but were not associated with PHN in the final adjusted model.[23] The case-base study found 13.5% of PHN cases and 4.7% of non-PHN controls had a cancer diagnosis 180 days before zoster[8]; after adjustment, cancer was associated with a reduced risk of PHN (adjOR: 0.1, 95% CI: 0.02-0.9); however, the CIs were wide. A meta-analysis for cancer effect estimates was not conducted as they involved different cancer sites.

3.3.4.5. Recent physical trauma

The only study to investigate this risk factor reported over 2-fold increased risk of PHN associated with experiencing trauma at the zoster site (contusions, burnings, wounds, and multiple traumas) within 6 months before study enrolment.[38]

3.3.4.6. Other

Other physical conditions investigated as predictors of PHN, but not included in the age-adjusted models included surgical intervention,[38] hepatitis-C virus infection,[38] hypertension,[26,38] neurological disorders,[38] allergy,[38] family history of coronary heart disease,[38] angina,[26] and chronic obstructive pulmonary disorder.[33]

3.3.5. Psychological comorbidities

These were assessed as risk factors for PHN in 4 studies. Two cohort studies assessed a range of psychological comorbidities; only personality disorder symptoms (adjOR: 1.09, 95% CI: 1.01-1.18),[27] and lower levels of trust in health care (adjOR: 1.01, 95% CI: 1.00-1.03)[35] showed a small association with PHN in multivariable analyses. Neither depression nor anxiety was included in multivariable analyses.[5,27,35,38]

3.3.6. Other risk factors

A cohort study found alipoprotein E-ε3 was more common and alipoprotein E-ε4 less common among female patients with zoster and PHN, suggesting that this host genetic factor may influence the risk of PHN.[50] One study found evidence that current/former smoking was associated with greater risk of PHN (adjOR: 2.08, 95% CI: 1.22-3.55)[38] whereas another included it in their final model, but did not report the association.[2] One study suggested a low state of varicella zoster virus (VZV)-specific

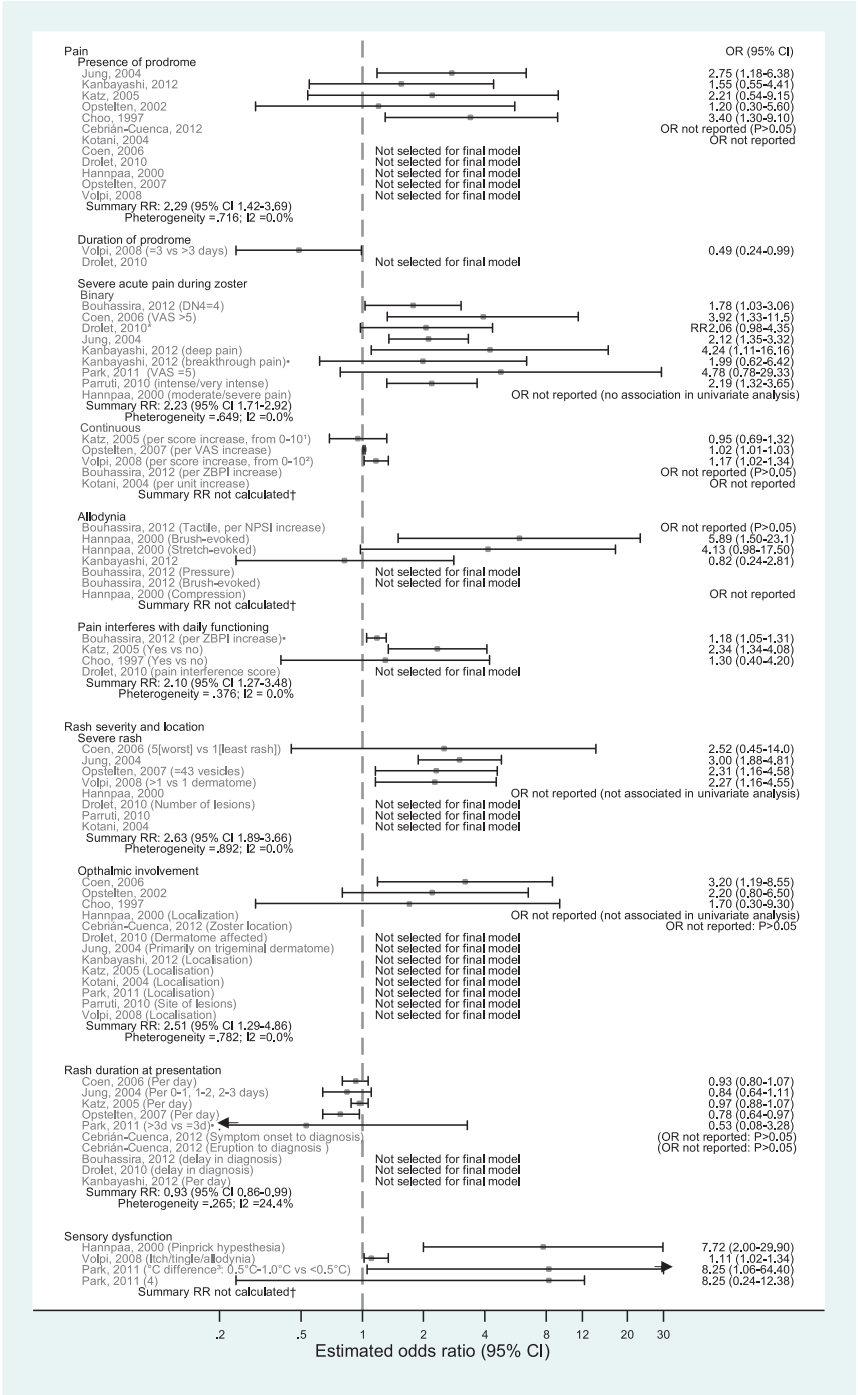

Figure 2. Summary of associations between postherpetic neuralgia and clinical features of acute zoster. [1]Composite score ranges from 0-100 numerical pain ratings and McGill Pain Questionnaire Present Pain [2]Intensity ratings of average and worst shingles pain. Intensity of pain using the Short Italian questionnaire, from 0-10. [3]Temperature differences are between normal and affected skin. [4]Percentage of body surface area thermal asymmetry (≥3 vs <3%). †Risk factors too varied to combine in meta-analyses. •Not included in summary RR (either because study has already contributed to meta-analysis, or exposure definition is not in-keeping with other studies). *Studies reporting RR (rather than OR) are not included in meta-analysis. CI, confidence interval; DN4, Neuropathic pain questionnaire with 4 questions; NPSI, Neuropathic pain symptom inventory score; OR, odds ratio; RR, rate ratio; SF-12, short-form 12; VAS, visual analogue scale ranging from 0 (non pain) to 100 (worst pain ever experienced); VZV, varicella zoster virus; ZBPI, Zoster brief pain inventory interference score.

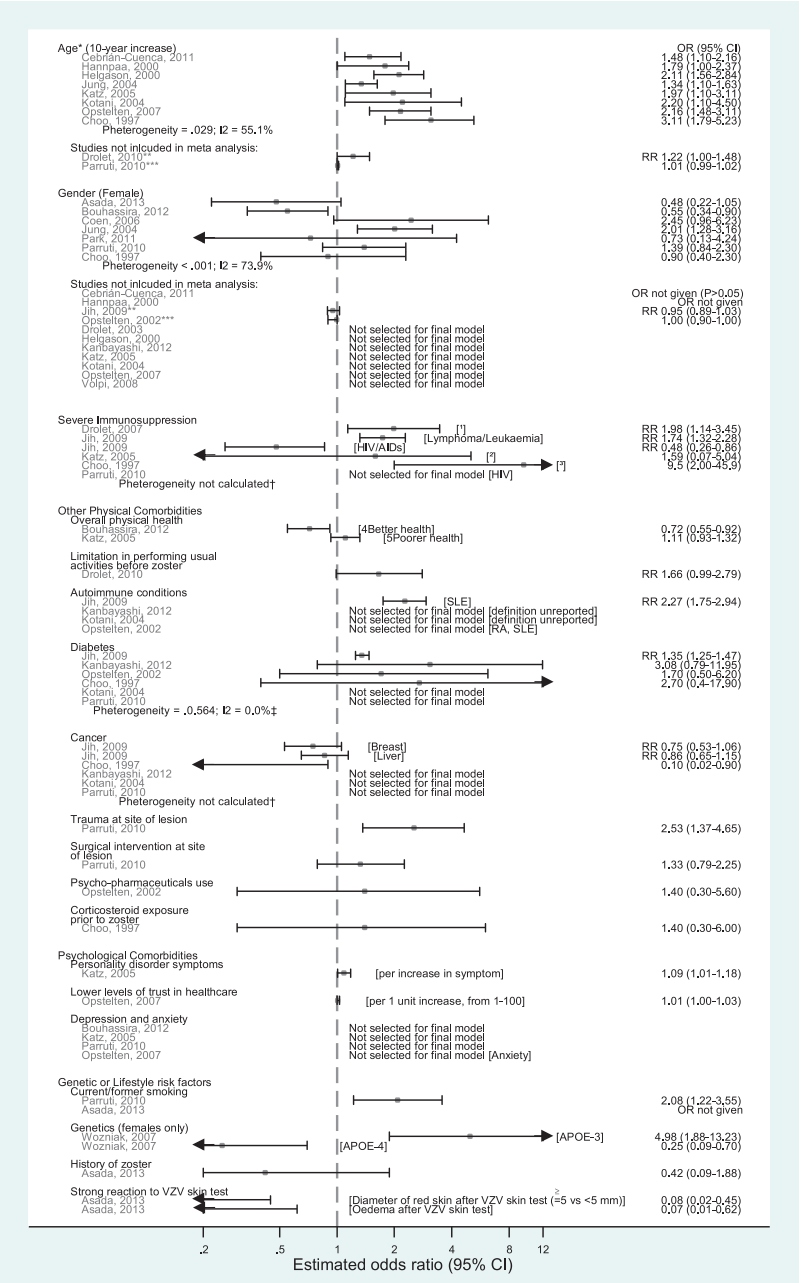

Figure 3. Summary of associations between postherpetic neuralgia and vaccine-targetable risk factors from identified studies. *Only 10/20 studies reported age such that the effect estimate could be converted into 10-year increases. Of the remaining 10 studies; 8 reported an increased risk of PHN with greater age, 1 showed no effect all, and 1 did not report an age-effect. **Studies reporting RRs rather than ORs not included in meta-analysis as RR can underestimate OR when outcome becomes common. ***Effect estimate from study may be erroneous therefore the study is not included in the meta-analysis: Parruti 2010 CIs are too narrow, and Opstelten 2002 confidence also too narrow. [1]Using high-dose oral corticosteroids or other immunosuppressive drugs, having invasive cancer or HIV/AIDS. [2]Undefined, however included HIV or currently being treated for cancer. [3]Connective tissue disease, HIV infection or organ allograft. [4]Better health: measured using continuous physical component summary score (higher scorer score reflects worse health). [5]Poorer health: measured using continuous variable of total number of medical conditions. †Risk factors too varied to combine in meta-analyses. ‡The large study by Jih et al. (N = 34,280) dominated the pooled relative risk contributing to 99·1% of the model. Other risk factors investigated as predictors of PHN, but not included in the final model, included; surgical intervention, hepatitis-C virus infection, hypertension, neurological disorders, allergy, family history of CHD, angina, chronic obstructive pulmonary disorder, education, alcohol abuse, familial status, years of education and race. APOE, alipoprotien E; CI, confidence interval; OR, odds ratio; RA, rheumatoid arthritis; RR, rate ratio; SLE, systemic lupus erythematosus.

PHN, Postherpetic neuralgia.

cell-mediated immunity, evidenced from reduced response to VZV skin-test, was associated with greater risk of PHN.[2] Studies investigating education,[13,27,38,46] race,[27] being married,[5,27,38] being in work,[13] consultation rate,[8,33] or alcohol abuse[38] did not select these risk factors in their final model.

Nine of the 19 studies had 2 or more definitions of PHN. Briefly, studies additionally defined PHN as pain at 1[6,8,13,21,33,35,38] (n = 7) and 6 months[9,21,28] (n = 3) after zoster onset; there were no major differences in study findings using these alternative definitions, except older age was a stronger risk factor for pain persisting 6 months, compared with 2 or 3 months, after zoster (Appendix Table A3, available online as Supplemental Digital Content at http://links.lww.com/PAIN/A132), indicating older age may be a risk factor for long-term PHN.

3.4. Assessment of bias

Our assessment of bias found 8/19 studies with at least 1 prespecified domain with a high risk of bias, 8 studies with at least 1 domain of medium risk, and 3 studies with only low or unclear risk of bias. Residual confounding by age was the most common source of potential bias, affecting 7/19 studies requiring age-adjustment (**Table 3**). Studies using electronic health care records were at greatest risk of reporting bias; specifically ascertainment bias, where outcome ascertainment relies on patients returning to their GP and higher general practice (GP) attendance could have increased the chance of PHN diagnosis.[8,23,26,33] Of the cohort studies, 5 experienced loss to follow-up of greater than 10% (**Table 3**). See Appendix Table A4 for detailed note on the bias assessment (available online as Supplemental Digital Content at http://links.lww.com/PAIN/A132).

The funnel plot gave a relatively symmetric pattern, suggesting that there was little indication of publication bias (**Fig. 4**). The distribution did not suggest that more extreme findings were being selectively published.

The sampling methods and patient characteristics of some studies suggest their external validity may be limited; characteristics of included patients indicate a nonrepresentative sample in some studies (Coen et al. reported that 20% of the study population was immunosuppressed[8] and in 3 studies over 30% of the cohort developed PHN[28,46,50]); 1 study used convenience sampling,[6] thus not all population members had an equal probability of being selected; and the number or characteristics of eligible patients refusing to participate were unclear in most studies.

4. Discussion

4.1. Summary of evidence

Our systematic review identified 19 prospective studies investigating risk factors for PHN. There was good evidence that clinical features of acute zoster including prodromal pain, severe

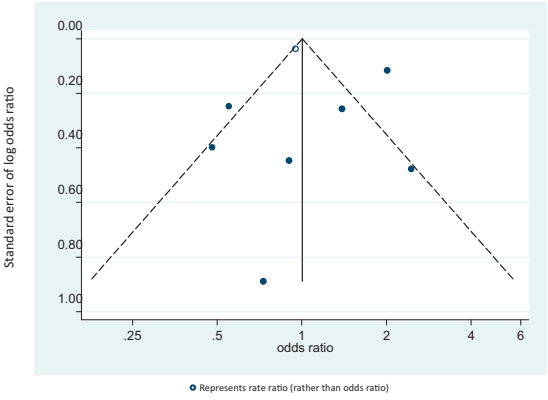

Figure 4. Assessment of publication bias for gender as a risk factor for postherpetic neuralgia. Funnel plot of the log odds ratio plotted against the standard error of the log odds ratio for seven studies reporting the effect of female gender on PHN risk (dotted line represents pseudo 95% confidence limits).

acute pain, severe rash, and ophthalmic involvement were associated with increased risk of PHN. Rash duration at zoster presentation was less strongly associated with PHN. Regarding vaccine-targetable risk factors, older age was consistently associated with PHN. The evidence for gender as a risk factor was conflicting. Immunosuppression and diabetes were significantly associated with PHN in a few, but not all studies. Systemic lupus erythematosus, recent trauma, and personality disorder symptoms were associated with PHN; however, evidence came from single studies only. No studies found evidence suggesting that depression or cancer was associated with increased risk of PHN. Most studies had small sample sizes reducing their power to detect associations. Our review highlights that we have a good understanding of which clinical features of zoster predict PHN, yet there is a need for better evidence on common and potentially easily vaccine-targetable risk factors for PHN prevention.

4.2. Interpreting the findings

It is believed that several pathophysiological mechanisms may contribute to the development of PHN. Acute zoster infection undoubtedly results in nerve damage to both the peripheral and central nervous system, yet the nature of the damage and specific mechanism resulting in persistent pain are not fully understood.[4] There are 2 (nonmutually exclusive) hypotheses for its development; the first is that persistence of VZV after acute zoster, at higher levels than during latency, causes continued pain; and the second, that after acute zoster infection, there is increased neuronal excitability and alteration of pain perception caused by neural damage.[1,20]

The variety of possible risk factors for PHN identified in the review may reflect these different mechanisms.[3] The finding that greater rash severity and greater acute pain are associated with increased risk of PHN supports the notion that greater neural damage caused by more severe infection contributes to the development of PHN.[15] That longer rash duration was associated with reduced risk of PHN initially seems inconsistent with the finding that more severe zoster rash is associated with PHN. However, late presentation might indicate patients had milder zoster not immediately demanding medical attention. Either way, this finding is unlikely to be due to the duration of the rash itself. Patients with ophthalmic zoster seem at greater risk of PHN, although it is not clear whether concerns about eye complications cause them to react differently, rather than the increased risk being driven by a biological mechanism.[20] Ageing undoubtedly causes a waning of cell-mediated immunity and may cause increased levels of the virus after zoster reactivation, potentially causing PHN. Other risk factors for PHN identified here are also associated with reduced cell-mediated immunity, including severe immunosuppression, systemic lupus erythematosus, and smoking. Trauma at the site of the rash may induce local changes facilitating reactivation of herpes zoster (HZ) and greater nerve damage leading to increased risk of PHN. However, the aetiological mechanism(s) by which these risk factors affect the development of PHN remains largely unknown.

4.3. Limitations of the selected studies

The included studies had some limitations. Many had small sample sizes, and we were unable to combine some results in a meta-analysis. Furthermore, many tested a number of risk factors; the associations observed may occur by chance due to testing multiple exposures. Most studies based zoster diagnosis on clinical opinion rather than serological or virological testing; this may have led to misclassification of patients with zoster; however, clinical diagnosis is typically reliable.[34]

Some studies may have been affected by specific biases. Age is a very strong predictor of PHN and yet 7/18 studies assessing age adjusted for it as a binary or categorical variable with wide age intervals, potentially causing residual confounding by age. Loss to follow-up affected 5/19 studies, and if loss to follow-up is associated with both PHN and the risk factor, bias could have been introduced.[18] Patients with PHN may be more likely to return for follow-up as they require continued care, and patients with particular risk factors may also return to their GP more commonly, making bias due to loss to follow-up likely. Ascertainment bias may have affected studies using routinely collected health care data. Here, spurious associations between PHN and medical conditions requiring regular contact with health care professionals may arise. One such study adjusted for health care utilisation[8] and still found a positive association with PHN and certain immunosuppressive disorders, suggesting the effect cannot be driven solely by ascertainment bias. Finally, not all studies adjusted for clinical features of the acute zoster episode,[2,21,23] and results may be subject to residual confounding.

4.4. Strengths and limitations of the review

This is the first study to systematically review the literature on risk factors for PHN; although clinical features of acute zoster have been acknowledged as risk factors for PHN, this is the first to summarise age-adjusted results and pool them in a meta-analysis. We undertook a comprehensive search of several databases using multiple keywords and indexed subject headings. The reliability of study selection criteria was confirmed by double screening of 10% of the articles.

There are some important limitations to this review. There is no consensus over the exact definition of PHN; in this review, PHN definitions ranged from pain persisting 1 to 6 months after rash onset, with some studies assessing *any* pain, whereas others required severe pain. A full assessment of risk factors by different PHN classifications was not possible here because of too few studies.

Between-study variability prevented us from pooling the effects of age and gender on PHN; there was some evidence that age of the study population contributed to the observed heterogeneity. However, these analyses were limited by the small number of studies and may have reduced our power to detect associations. Variability may be due to different adjustment for confounders or some studies reporting biased effect estimates, eg, due to PHN measurement error or loss to follow-up. Studies also used different definitions for certain clinical features of acute zoster, such as severe acute pain and severe rash, potentially giving some heterogeneity to the results.

Our search strategy may have missed some studies; however, we used multiple databases (including grey literature) and searched reference lists of selected articles, to minimise this issue. As with any literature review, studies finding no effects may have gone unpublished. Our funnel plot did not demonstrate any evidence of publication bias with respect to assessing gender as a risk factor for PHN. However, publication bias may affect other risk factors differently, and there were not enough studies per risk factor to assess this for other exposures. Finally, non–English-language articles were excluded because of resource limitations; however, the authors believe it is unlikely to have led to the omission of any major articles in the area.

4.5. Implications

Zoster vaccination offers a way of preventing this debilitating complication by preventing zoster itself, but is currently

expensive; therefore, targeting the vaccine toward groups at high-risk of PHN may be beneficial. The vaccine is currently licensed in certain countries in the European Union, United States, and Australia.[49] It is targeted at older age groups and contraindicated in patients with severe immunosuppression. As older age is the only indisputable risk factor that vaccination policies can use, this approach seems reasonable. If patients with severe immunosuppression are at increased risk of PHN as suggested by this review, in addition to being at greater risk of zoster itself, there is even more need to identify alternative strategies to prevent zoster in these groups.

This review has highlighted our lack of understanding of vaccine-targetable risk factors for PHN, and the need to perform studies exploring suggested associations. Such studies would need to be generalizable to a wide group, by recruiting patients aged 18 and over and including immunosuppressed patients, to examine the risk of PHN by age and immunosuppression status. Other desirable features would include recruiting a large number of individuals to achieve greater power to help detect small effects, collecting data on all known and possible risk factors for PHN, actively following up patients with zoster to allow persistent pain to be identified for the entire cohort at the same time and reducing loss to follow-up to avoid differential ascertainment of PHN. Finally, at the analysis stage, detailed adjustment for age using either a continuous or finely categorised age variable would reduce residual confounding by age.

5. Conclusions

This study confirms that features of the acute zoster episode, including prodromal pain, severe rash, severe acute pain, and ophthalmic involvement are risk factors for PHN. Our current understanding of vaccine-targetable risk factors for PHN is however limited. There are some suggestions that immunosuppression, systemic lupus erythematosus, diabetes, and recent trauma may be associated with greater risk of PHN. Increasing age is the only established risk factor for PHN that has been quantified with sufficient rigour as to usefully inform vaccine policy. Larger studies with greater power to detect associations, and studies addressing the limitations of previous research, may elucidate some of the unknown risk factors for PHN.

Conflict of interest statement

The authors have no conflicts of interest to declare.

This article presents independent research supported by an NIHR Clinician Scientist Fellowship (to Doctor Langan, grant number: NIHR/CS/010/014). The study was approved by ISAC (application no. 11,028) and the London School of Hygiene and Tropical Medicine [application no. 5930]. K. Bhaskaran is supported by an NIHR postdoctoral fellowship (PDF-2011-04-007). L. Smeeth is supported by a Wellcome Trust senior research fellowship in clinical science. S. L. Thomas was supported by an NIHR Career Development Fellowship (CDF-2010-03-32). All authors performed this research independently of the funding bodies. 6.3. Published appendices

Data extraction details

The following data were extracted for the selected studies by HF; study characteristics including, study design, country and year(s) of study, study size, study population (including mean age and range), definition and method of ascertaining zoster cases, risk factors assessed and how they were ascertained, definition and method of ascertaining PHN, % with PHN, and statistical analysis. We extracted all study results from the final age-adjusted model, including the multivariable effect estimates when available (e.g. adjusted relative risks (RR), or odds ratios (OR) with 95% confidence intervals (CI)) and any other relevant analysis (such as sub-group analysis or investigation of effect modification).

Risk of bias assessment details

The risk of bias was assessed separately for each study using the following pre-specified domains; residual confounding by age, selection bias, exposure and outcome information bias and bias due to missing data. We formulated our assessment based on the Cochrane Collaborations approach, where domains are categorised as having; “High risk” (bias may alter the results seriously), “Medium risk” (bias may alter the results moderately), “Low/No risk” (bias, if present, is unlikely to alter the results seriously) or “Unclear risk” (a risk of bias that raises some doubt about the results). Support for each judgement of risk is provided in the appendix (Table A3).

Letter to authors

Dear *[author name]*

I am carrying out a systematic review of studies investigating risk factors for postherpetic neuralgia (PHN). This is part of my PhD on zoster epidemiology, and we also aim to publish the review as a paper. I have identified the studies to be included in the review, one of which is the following study in which you are listed as corresponding author:
[*Reference*]

I am now extracting data from study reports to summarise in the review. I would be most grateful if you could clarify a few points (listed below) regarding your methods and results?
[Specific questions]

Your help would be greatly appreciated as I am keen to summarise your study as accurately and completely as possible.

Many thanks
Harriet

Table A2: Sub group meta-analyses to identify causes of heterogeneity for effect of age and gender on PHN.

	No. of studies	Summary RR (95% CI)	Pheterogeneity; I^2	P-value from meta-regression (univariate)
Age				
All studies	8	-	P=0.029; 55.1%	-
Mean age of study population				
≥60 years	3	2.39 (1.81-3.16)	P=0.533; 0.0%	
<60 years	3	1.46 (1.24-1.73)	P=0.242; 29.4%	0.08
Definition of PHN				
Pain at 4 months	3	1.45 (1.21-1.73)	P=0.195; 38.9%	
Pain at 3 months	3	1.80 (1.48-2.20)	P=0.305; 15.8%	0.52
Ascertainment of PHN				
Self-reported	6	1.63 (1.44-1.85)	P=0.079; 49.3%	
Medical records	1	3.11 (1.82-5.31)	-	0.14
Excluded immunosuppressed				
Yes	2	1.41 (1.18-1.68)	P=0.235; 29.1%	
No	4	1.96 (1.62-2.37)	P=0.126; 47.6%	0.23
Source population from primary care				
Yes	5	1.97 (1.67-2.33)	P=0.188; 35.0%	
No	2	1.39 (1.15-1.68)	P=0.186; 42.8%	0.18
Gender				
All studies	7	-	P=0.01; 73.9%	-
Mean age of study population				
≥60 years	2	0.62 (0.40-0.95)	P=0.335; 0.0%	
<60 years	3	1.65 (1.19-2.30)	P=0.364; 1.0%	0.04
Definition of PHN				
Pain at 4 months	1	2.01 (1.28-3.16)	-	
Pain at 3 months	3	0.68 (0.47-0.99)	P=0.013; 77.0%	0.45
Ascertainment of PHN				
Self-reported	6	1.13 (0.88-1.44)	P=0.000; 78.1%	
Medical records	1	0.90 (0.38-2.16)	-	0.83
Excluded immunosuppressed				
Yes	1	2.01 (1.28-3.16)	-	
No	6	0.88 (0.66-1.16)	P=0.018; 63.5%	0.25
Source population from primary care				
Yes	3	0.78 (0.53-1.15)	P=0.020; 74.5%	
No	3	1.36 (0.93-1.99)	P=0.006; 80.4%	0.97

Table A3: Association between PHN and various risk factors: risk factors, adjusted effect measure and 95% confidence interval by study. All risk factors included in the final multivariate model are listed, unless otherwise specified

	PHN definition	Age (in years)	Gender	Severe immune suppression	Other physical or psychological comorbidities	Genetic or lifestyle risk factors	Other "non-vaccine targetable" risk factors in final model
Cohort studies - risk factor: odds ratio (95% CI) unless specified							
Cebrián-Cuenca 2011[2]	3m (main results)	Per yr increase: 1.04 (CI 1.01-1.08, P<0.03)	Gender: OR not given P>0.05				Antiviral use: OR not reported P>0.05.
	1m	Per yr increase: 1.04 (CI not given, P<0.01)	Gender: OR not given P>0.05				Time interval (days) between symptom onset and clinical diagnosis: 1.11, P<0.01 Antiviral use: OR not reported P>0.05.
Coen 2006	3m (main results)	Age over 50 yrs: 3.91 (1.38-11.11)	F vs M: 2.45 (0.96-6.23)	-	-	-	Extent of rash score: not associated, ophthalmic branch involvement: 3.20 (1.19-8.55), VAS >5: 3.92 (1.33-11.5), VAS>5 and or age over 50: 8.51 (1.11-65.2), time from onset of rash (days): 0.93 (0.80-1.07).
	6m	Age over 50 years: 13.8 (1.74-110)	F vs M: 5.21 (1.38-19.6)	-	-	-	Extent of rash score: not associated, ophthalmic branch involvement: 5.31 (1.66-16.9), VAS >5: 3.68 (1.01-13.5), VAS>5 and or age over 50: 4.74 (1.59-38.2), time from onset of rash (days): 0.78 (0.61-1.00).
Drolet 2010	3m (main results)	Per yr increase: RR1.02 (1.00-1.04)	Not in final model: No association in univariate analyses	General immune suppression (using high dose oral corticosteroids or other immunosuppressive drugs, having invasive cancer or HIV/AIDS): RR 1.98 (1.14-3.45) (sensitivity analysis)	Limitation in performing usual activities before zoster: RR 1.09 (1.01-1.18) Not in final model: No association with having another pain condition or other pre-zoster EQ-5D measures in univariate analyses.	Income, baseline ≥50,000 USD: $40K-49,999: RR 2.24 (0.98-5.13) $20K-39,999: RR 1.77 (0.87-3.63) <$20K: 1.85 (0.89-3.83) Not in final model: No association with working status or education in univariate analyses.	Severe acute pain at zoster: RR 2.06 (0.98-4.35)
	30 days (RRs not reported)	Older age associated with PHN	-	-	-	-	Severe acute pain at zoster associated with PHN Limitation in performing usual activities at recruitment associated with PHN
Helgason 2000	3m (main results)	Per 10 yr increase: 2.11 (1.56-2.84)	Not in final model: No association in univariate analyses	-	-	-	-
	1m	1.87 (1.56 to 2.23)	Not in final model: No association in univariate analyses	-	-	-	-
	6m	2.45 (1.50-4.01)	Not in final model: No association in univariate analyses	-	-	-	-
	12m	2.33 (1.48-3.69	Not in final model: No association in univariate analyses	-	-	-	-

NB: Reference category listed last. yr=year, SLE=Systemic Lupus Erythematosus [1]PCS=physical component summary score, MCS= mental component summary score (a patient reported survey of physical/mental health using Short Form 12 (SF-12): score <50 represented below-average health status) [2]Variables included in the final model, and whether the final model was restricted to immunocompetent patients, is unclear. [3]Adjusted for age and gender only [4]Study used ordered logistic regression, therefore the parameters represent the exposure ORs for being the highest outcome categories, compared to the lowest outcome categories: it is assumed the effect of exposure is the same for all splits of the outcome categories.
[5]Physical Health measured using the Life Stressors and Social Resources Inventory, which sums the total number of patient reported medical conditions.

Table A3: (continued)

	PHN definition	Age (in years)	Sex	Severe immune suppression	Other physical or psychological comorbidities	Genetic or lifestyle risk factors	Other risk factors in final model
Cohort studies (continued)							
Kotani 2004	2m	Per 10 yr increase: 2.2 (1.1-4.5)	Not in final model (no association in univariate analyses)	-	Not in final model: no association with diabetes, malignancy or autoimmune disease in univariate analyses	-	-
	6m	Per 10 yr increase: 2.7 (1.2-5.7)	Not in final model (no association in univariate analyses)		Not in final model: no association with diabetes, malignancy or autoimmune disease in univariate analyses		
	12m	Per 10 yr increase: 2.7 (1.2-6.2)	Not in final model (no association in univariate analyses)		Not in final model: no association with diabetes, malignancy or autoimmune disease in univariate analyses		
Opstelten 2002	3m	≤54: 1.00 55-74: 5.4 (1.1-26.5) ≥75: 19.7(4.3-90.9)	F vs M: 1.0 (0.9-1.0)	-	Diabetes:1.7 (0.5-6.2) Psycho-pharmaceuticals use: 1.4 (0.3-5.6) Not in final model: no association with chronic obstructive pulmonary disease, rheumatoid arthritis, systemic lupus erythematosis, psychological problem or corticosteroid use at zoster diagnosis in univariate analyses.	-	Localization, ophthalmic vs not:2.2 (0.8-6.5), Painful prodrome: 1.2 (0.3-5.6)
	1m	≤54: 1.00 55-74: 4.2 (1.8-9.7) ≥75: 10.7(4.6-25.1)	F vs M: 0.8 (0.4-1.5)	-	Diabetes:1.4 (0.6-3.8) Psycho-pharmaceuticals use: 1.4 (0.5-3.9) Not in final model: no association with chronic obstructive pulmonary disease, rheumatoid arthritis, systemic lupus erythematosis, psychological problem or corticosteroid use at zoster diagnosis in univariate analyses.	-	Localization, ophthalmic vs not:2.3 (1.1-4.6), Painful prodrome: 2.1 (0.9-5.2)
Opstelten 2007	3m	Per y: 1.08 (1.04-1.12)	Not in final model: No association in univariate analyses	-	Trust in healthcare score, 1 unit increase from 0-100: 1.01 (1.00-1.03) Not in final model: psychological predictors not associated in univariate analyses.	-	Duration of rash prior to consultation, in d: 0.78 (0.64-0.97), Severe rash, ≥43 vesicles: 2.31 (1.16-4.58), Severity of acute pain, per vAS unit: 1.02 (1.01-1.03)
	1m (ORs not available)	Same as above, except age not associated with PHN and epidural injection was associated with PHN.					
Parruti 2010	1-3m	Per 10 y increase: 1.01 (0.99-1.02)	F vs M: 1.39 (0.84-2.30)	Not in final model: No association with HIV in univariate analyses.	Trauma at site of lesion:2.53 (1.37-4.65) Surgical Intervention at site of lesion: 1.33 (0.79-2.25) Not in final model: no association with HCV infection, hypertension, diabetes, neoplasm, neurological disorders, psychiatric illness, allergy or family history of major cardiovascular events, malignancies, neurological diseases, major depression, at univariate analysis.	Current/former smoking: 2.08 (0.22-3.55) Not in final model: no association with alcohol abuse, familial status, educational level in univariate analyses.	Intense/very intense pain at presentation:2.19 (1.32-3.65), Missed antiviral prescription: 2.28 (1.04-4.98)

Table A3: (continued)

Case base studies - risk factor: prevalence ratio (95% confidence interval)							
Choo 1997††	60 days	Per y: 1.12 (1.06-1.18)	F vs M: 0.9 (0.4-2.3)	Connective tissue disease, HIV infection or organ allograft: 9.5 (2.0-45.9)	Diabetes: 2.7 (0.4-17.9) Cancer: 0.1 (0.02-0.9) Corticosteroid exposure prior to zoster: 1.4 (0.3-6.0)	-	Prodromal symptoms: 3.4 (1.3-9.1). [In final model, but no evidence of association with PHN in multivariate analysis (confidence intervals overlapped the null): number of encounters previous 180d, dermatome affected, interference with activities on daily living, complications including superinfection and ocular complications and other, acyclovir exposure, corticosteroid exposure after zoster]
	30 days	Per y: 1.09 (1.06-1.12)	F vs M: 1.3 (0.6-2.7)	Connective tissue disease, HIV infection or organ allograft: 3.1 (1.0-9.5)	Diabetes: 2.1 (0.6-7.7) Cancer: 0.2 (0.1-0.8) Corticosteroid exposure prior to zoster: 2.9 (0.7-11.3)	-	Prodromal symptoms: 2.1 (1.1-4.3). [In final model, but no evidence of association with PHN in multivariate analysis (confidence intervals overlapped the null): number of encounters previous 180d, dermatome affected, interference with activities on daily living, complications including superinfection and ocular complications and other, acyclovir exposure, corticosteroid exposure after zoster]

NB: Reference category listed last. Yr=year, HCV=Hepatitis C virus, APOE=alipoprotien E. ††Adjusted for age (continuous variable), presence (yes or no) of prodromal symptoms, severe pain, or comorbid conditions; and number of healthcare encounters.

Table A4: Assessment of bias: detailed notes

Type of bias	Confounding Residual confounding by age	Selection Bias Loss to follow-up	Exposure information bias Non-differential misclassification	Outcome (PHN) information bias Reporting bias	 Non-differential misclassification	Bias due to missing data Missing exposure data
Cohort studies						
Asada 2013	O Age adjusted using categorical variable (50-, 60-, 70, ≥80)	O 4% of cohort lost to follow-up	O Several dermatologists collected exposure information: differences between physician recording practices may lead to different exposure ascertainment	O -Outcome assessed using a standard scale for pain -Unclear if patients were aware of study hypothesis or those ascertaining outcome were aware of exposure status assessment.	? Definition of pain may vary between patients	◆ Over half patients had missing data for VZV skin test reaction tests; Impact of missing data not presented.
Bouhassira 2012	◆ Age adjusted using binary variable	■ 20% of cohort lost to follow-up: no information on non-responders	O Several risk factors assessed: some errors are possible	O -Outcome assessed using a standard question -Unclear if patients were aware of study hypothesis or those ascertaining outcome were aware of exposure status	? Definition of pain may vary between patients	? Missing data not described for all exposure variables; 36% of PHN patients and 28% non-PHN patients missing data on depression. Impact of missing data not presented.
Cebrián-Cuenca 2011	O Age adjusted using continuous variable	■ 15% of cohort lost to follow-up	O Some information from medical record review; differences between physician recording practices may lead to different exposure ascertainment	O -Outcome ascertained from patient reported pain symptoms -Unclear if patients were aware of study hypothesis or those ascertaining outcome were aware of exposure status	? Definition of pain may vary between patients	O No missing data
Coen 2006	◆ Age adjusted using binary variable	O 3% of cohort lost to follow-up	? Unclear who collected exposure data	O -Outcome ascertained from patient reported pain symptoms -Unclear if patients were aware of study hypothesis or those ascertaining outcome were aware of exposure status	? Definition of pain may vary between patients	? Missing data not reported for all exposure variables
Drolet 2010	O Age adjusted using continuous variable	O No loss to follow-up	O Several risk factors assessed: some errors are possible	O -Outcome assessed using a standard questionnaire -Unclear if patients were aware of study hypothesis	? Definition of pain may vary between patients	■ Missingness reported if exposures had 10 + missing values. Income missing for 28 patients (11%); included missing category in analyses which may cause bias.

Table A4: Assessment of bias: detailed notes (continued)

Type of bias	Confounding Residual confounding by age	Selection Bias Loss to follow-up	Exposure information bias Non-differential misclassification	Outcome (PHN) information bias Reporting bias	 Non-differential misclassification	Bias due to missing data Missing exposure data
Cohort studies						
Haanpaa 2000	O Age adjusted using continuous variable	■ 18% of cohort lost to follow-up	O Unclear how age and sex were assessed, however unlikely to be misclassified	■ -Outcome ascertained from patient reported pain symptoms -Study investigator those ascertaining outcome was aware of exposure status	? Definition of pain may vary between patients	? Missing data not reported for all exposure variables
Helgason 2000	O Not applicable: no multivariable analysis	O 7% of cohort loss to follow-up: no information on non-responders	O Unclear how age and sex were assessed, however unlikely to be misclassified	O -Outcome ascertained from patient reported pain symptoms -Unclear if patients were aware of study hypothesis or those ascertaining outcome were aware of exposure status	? Definition of pain may vary between patients	O No missing data
Jih 2009	◆ Age adjusted using binary variable	? Unclear if any zoster patients were lost to follow-up during 90d following zoster episode: e.g. patients may have moved or died.	? Based on claims data where coding has not been validated: possibility of exposure information being rule-out codes (e.g. unusually high rate of diabetes (20.6%) in the study population).	◆ -Physicians recording PHN not aware of study hypothesis -Ascertainment bias: Patients with exposures (e.g. diabetes) may have higher medical attendance than healthy zoster patients, thus more likely to be ascertained in claims data, a spurious association	◆ No ICD-9 code for PHN, therefore based on zoster code plus neuralgia treatment. Physicians may have various other ways of recording PHN.	? Missing data not reported
Jung 2004	O Age adjusted using continuous variable	■ 11% of cohort lost to follow-up: generally comparable to those with complete data, except being on average 4 years younger	O Unlikely	O -Outcome ascertained from patient reported pain symptoms -Patients originally recruited into clinical trial of antiviral effectiveness thus unlikely to be influenced by these study hypotheses	? Definition of pain may vary between patients	O Missing data not available: likely to be minimal (from email correspondence)

Table A4: Assessment of bias: detailed notes (continued)

Type of bias	Confounding Residual confounding by age	Selection Bias Loss to follow-up	Exposure information bias Non-differential misclassification	Outcome (PHN) information bias Reporting bias	 Non-differential misclassification	Bias due to missing data Missing exposure data
Cohort studies						
Kanbayashi 2012	◆ Age adjusted using categorical variable (<50, 51-74, ≥75)	O No loss to follow-up	◆ Exposure information from clinical records; differences between physician recording practices may lead to different exposure ascertainment. Furthermore, it is unclear whether this initial visit, when exposures were defined, is for acute zoster or whether these patients already have PHN.	? -Unclear how pain defined, however ascertainment bias possible: i.e. patients with exposures (e.g. diabetes) may have higher medical attendance than healthy zoster patients, thus more likely to be diagnosed with PHN, causing a spurious association -Physicians recording PHN not aware of study hypothesis	◆ PHN was ascertained from medical record of documented pain: clinicians may record symptoms differently	O No missing data reported
Katz 2005	O Age adjusted using continuous variable	O 8% of cohort lost to follow-up: no major differences in exposures compared to those completing follow-up	■ Several risk factors assessed: some errors are possible. Exposures recorded on average 17 days following rash onset: measures of pre-morbid functioning may be biased	■ -Outcome ascertained from patient reported pain symptoms -Some outcome assessments carried out by psychologist aware of exposure status -Unclear if patients aware of study hypotheses	? Definition of pain may vary between patients	O Missing exposure data imputed for multivariate analyses: similar results obtained with complete case analysis
Kotani 2004	O Age adjusted using categorical variable (per 10year increase)	O No loss to follow-up	? Method of ascertaining exposures is unclear	? -Unclear how pain was ascertained -Unclear if interviewers know exposure status -Unclear if patients aware of study hypotheses	? Definition of pain may vary between patients	? Missing data not reported
Opstelten 2002	◆ Age adjusted using categorical variable (≤54, 55-74, ≥75)	O No loss to follow-up	O Exposure information from clinical records; differences between physician recording practices may lead to different exposure ascertainment.	◆ -Physicians recording PHN not aware of study hypothesis -Ascertainment bias: Patients with exposures (e.g. diabetes) may have higher medical attendance than healthy zoster patients, thus more likely to be ascertained in claims data, causing a spurious association. Under-capture of PHN likely, indicated by very low incidence of PHN in zoster patients; may be related to exposure status	◆ PHN defined as recording of pain or analgesic; clinicians may record symptoms / prescribe medicine differently	■ Certain exposures (eg prodromal symptoms) may not be routinely recorded by clinician: more likely to reduce statistical power

Table A4: Assessment of bias: detailed notes (continued)

Type of bias	Confounding Residual confounding by age	Selection Bias Loss to follow-up	Exposure information bias Non-differential misclassification	Outcome (PHN) information bias Reporting bias	 Non-differential misclassification	Bias due to missing data Missing exposure data
Cohort studies						
Opstelten 2007	O Age adjusted using continuous variable	O No loss to follow-up	O Unlikely	O -Outcome ascertained from patient-completed questionnaire -Unclear if patients aware of study hypotheses	? Definition of pain may vary between patients	■ 127 patients had missing values for ≥1 variables: details of missingness not reported. Missing data was singly imputed
Park 2011	◆ Age adjusted using binary variable	O No loss to follow-up	? Unclear how exposures assessed	? -Unclear how outcome assessed -Unclear if patients aware of study hypotheses	? Definition of pain may vary between patients	? No information on completeness of exposure data
Parruti 2010	O Age adjusted using categorical variable (per 10 year increase)	O 6% of cohort lost to follow-up: no information on non-responders	O Unlikely	O -Outcome ascertained from patient reported pain symptoms -Unclear if patients were aware of study hypothesis or those ascertaining outcome were aware of exposure status	? Definition of pain may vary between patients	■ Some missing exposure data: impact on findings unclear
Volpi 2008	◆ Age adjusted using binary variable	◆ 41% of cohort lost to follow-up: no information on non-responders	O Unlikely	O -Outcome ascertained from patient reported pain symptoms -Unclear if patients were aware of study hypothesis or those ascertaining outcome were aware of exposure status	? Definition of pain may vary between patients	■ Some missing exposure data: impact on findings unclear
Wozniak 2007	O Confounding by age n/a in genetic studies: confounding by population possible, yet selected Caucasian patients	? No loss to follow-up	O Objective measures of exposure: unlikely to be biased	? -Unclear if researchers are aware of exposure status	? Definition of pain may vary between patients	O No missing data not reported

Table A4: Assessment of bias: detailed notes (continued)

Case-base study						
	Residual confounding by age	**Loss to follow-up and selection of base population**	**Non-differential misclassification**	**Reporting bias**	**Non-differential misclassification**	**Missing exposure data**
Choo 1997						
	Age adjusted as continuous variable	No loss to follow-up reported. Randomly selected non-PHN patients from all eligible zoster patients	Exposure information from clinical records; differences between physician recording practices may lead to different exposure ascertainment.	Ascertainment bias: Patients with exposures (e.g. diabetes) may have higher medical attendance than healthy zoster patients, thus more likely to be diagnosed with PHN, causing a spurious association. However authors adjusted for healthcare utilisation.	Physicians may have various ways of recording PHN; however authors identified potential PHN cases using a broad criteria, before screening their medical records for evidence of PHN	Certain exposures (eg prodromal symptoms) may not be routinely recorded by clinician: could reduce statistical power

6.4. Review of studies assessing risk factors for postherpetic neuralgia within general population samples

6.4.1. Introduction

The risk of PHN in the general population is made up of two parts; first, the risk of zoster and second, the risk of PHN, *once you have zoster*. In general population based studies, it is not immediately clear whether any identified risk factors are simply predictive of zoster itself, and hence associated with a higher risk of PHN, or whether they are specifically risk factors for developing PHN.

However, in terms of zoster vaccine policy, understanding risk factors for PHN in the general population may be valuable. The vaccine is, after all, not useful once a patient develops zoster, therefore vaccination policies ideally need to identify groups of patients at high risk of PHN within the general population.

In this section, papers excluded from the published systematic review solely because they examined risk factors for PHN in a general population sample, were summarised.

6.4.2. Methods

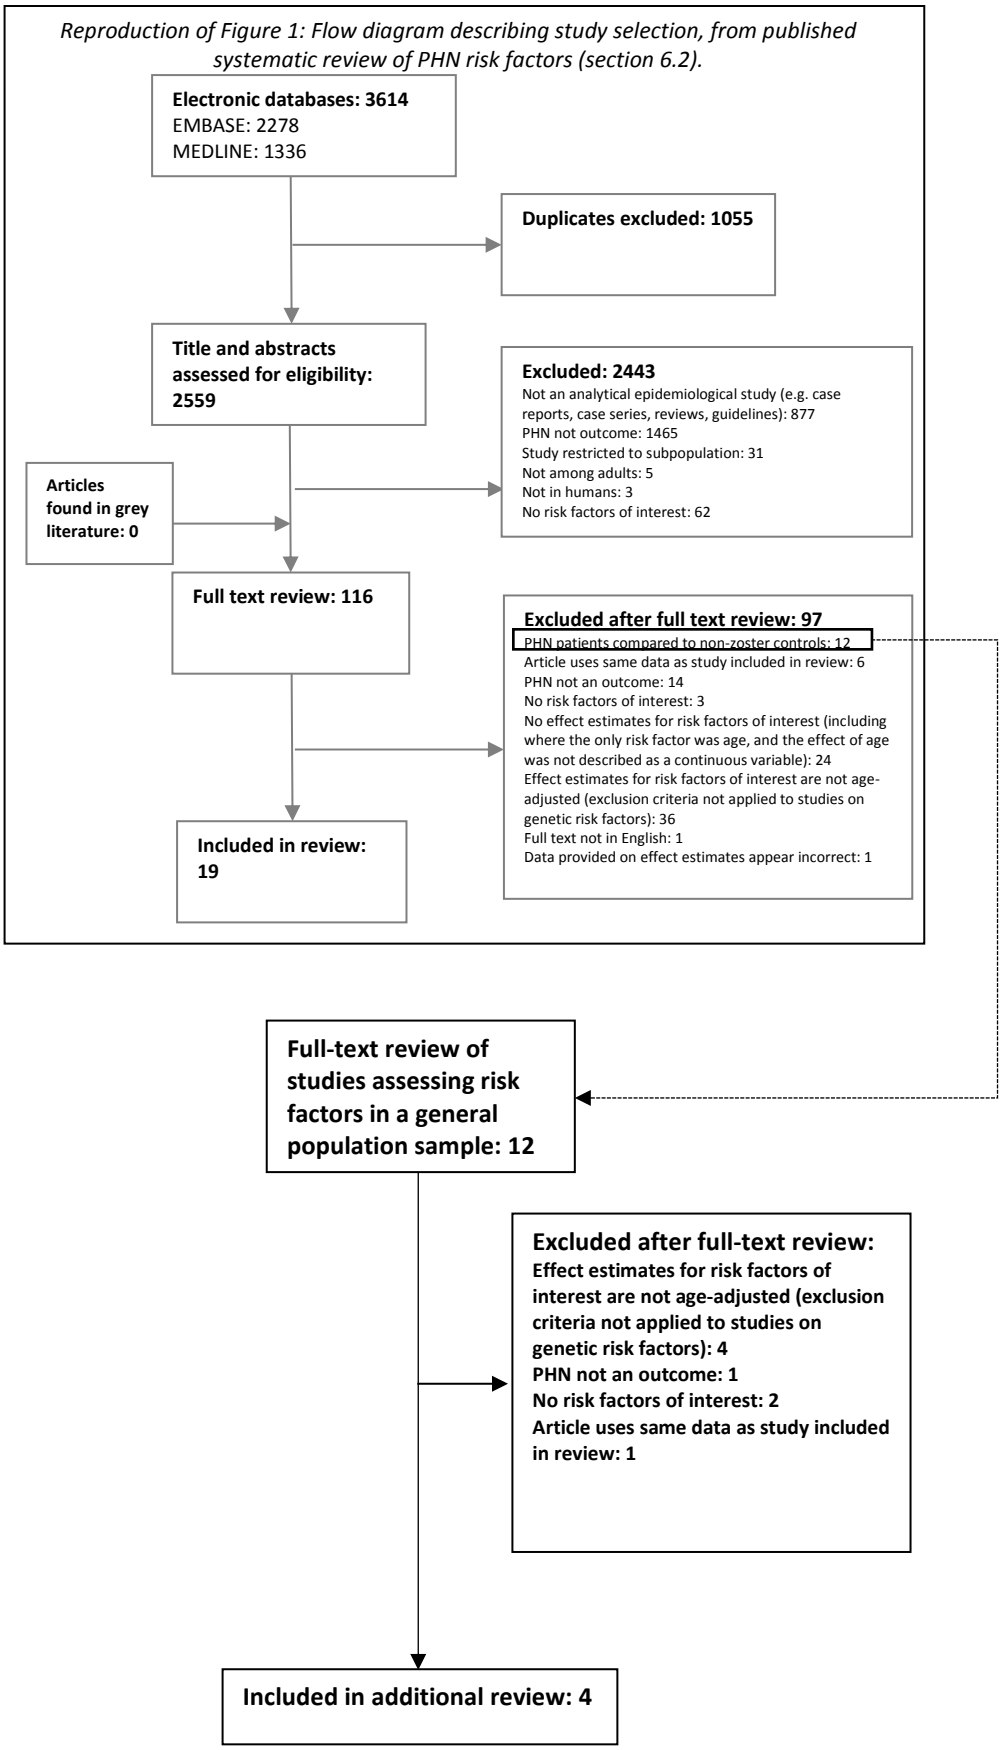
Full details of the methods are explained in the paper, "Systematic review and meta-analysis of risk factors for postherpetic neuralgia", in section 6.2. The same inclusion and exclusion criteria were applied, except that the selected studies were those that compared PHN patients to a general population sample, rather than comparing PHN patients to zoster patients without PHN. Risk of bias assessment was based on the Cochrane Collaboration approach, where each study is assessed individually for pre-specified bias domains.

6.4.3. Results

In the published systematic review of PHN risk factors (section 6.2) twelve studies were identified which were based in a general population sample, that is, they compared PHN patients to the general population (see figure 5). These 12 studies were re-reviewed to identify those meeting the inclusion criteria (see section 6.4.2. above). Four of the 12 studies were

excluded as they did not adjust for age; these studies explored the association between PHN and plasma vitamin C levels,[165]

Figure 5: Flow diagram describing study selection for additional review of studies assessing risk factors for PHN in a general population sample



nutrient deficiencies,[166] residual scarring[167] and impaired glucose metabolism.[168] Two studies used the same data, therefore only one of these reports was retained (one was a conference paper and thus excluded[169]). Two studies had no risk factors of interest (these risk factors specifically, were, VZV DNA and viral microarray-based transcriptomal measurements).[170,171] Finally, another paper was excluded because after further review, PHN was deemed to be the exposure, rather than the outcome.[172]

Four studies met the inclusion criteria. Three were case-control studies and one used a cohort study design. The characteristics of these studies are described in Table 4 and their results are outlined in Table 5.

6.4.3.1. Study findings

All three case-control studies looked at genetic susceptibility to PHN. They all recruited PHN patients from outpatient hospital clinics. Two studies assessed genes in the human leukocyte antigen (HLA) class I and II regions as predictors of genetic susceptibility for PHN in Japanese individuals, comparing individuals with PHN to patients with no history of zoster.[173,174] Both studies reported associations between alleles within the HLA region and PHN. Another study found no evidence that PHN patients were more likely to have a family history of zoster than age and gender-matched controls (with no history of zoster themselves), suggesting susceptibility to PHN may not be inherited.[175]

The cohort study used Israeli EHR data from primary and secondary care, to follow-up over one million patients during 2010 for PHN.[50] Age was the strongest risk factor for PHN, with people between 65-74 years >20 times as likely to get PHN compared to patients aged 25-34 (hazard ratio (HR) 20.9, 95%CI 11.0-39.6). Females and patients of higher SES were more likely to be diagnosed with PHN. HIV treatment and having a history of cancer in the last five years were strongly associated with PHN risk and the authors reported a borderline association between diabetes and PHN (HR 1.35, 95%CI 0.99-1.83).

6.4.3.2. Assessment of bias

Case control studies

In the genetic association study by Ozawa *et al* (n=168), it is unclear how the controls were selected. Sato et al specified that the controls were selected from the same hospital as the cases, potentially reducing the possibility of selection bias as controls are likely to come from the same source population as the cases. However, the authors did not specify the reason

controls were visiting hospital, so it is not possible to assess if controls are likely to have an association with the exposure (HLA class I and II regions).

Despite major differences in the age of the cases (68.3 years) and their controls (40.1 years) in the study by Sato *et al* (n=165), there were no associations between age and the haplotypes proposed as risk factors for PHN; thus the results are unlikely to be due to confounding by age. In the case-control study by Gatti *et al,* assessing family history as a risk factor for zoster, the researchers matched on age at the design stage. However, it is unclear how age was accounted for at the analysis stage; hence there may be residual confounding by age. The study also relied on patient recall from years (although the number of years was not specified) previously; therefore, misclassification of exposure status is likely, which may lead to underestimation of effects.

Cohort study

In the Israeli cohort study[50] PHN was defined as any patient with an ICD-9 code for PHN anytime during 2010. In practice, physicians may use general zoster or pain codes to record PHN.[102] Patients with a specified PHN code are unlikely to be systematically different to PHN patients with other codes, therefore this would cause non-differential misclassification of the outcome and reduction in the effect sizes. PHN codes were also selected without reference to the timing of acute zoster and the authors report physicians tended to use a 1-month definition of PHN. As a result, their findings may not reflect risk factors for the most commonly used definition of PHN (pain persisting for three months after zoster). There is also a possibility of ascertainment bias; that patients with risk factors of interest may seek healthcare more frequently and increase their likelihood of PHN diagnosis.

The cohort study utilised a database that is broadly representative of the Israeli population in terms of age and sex, therefore the results are likely to be generalizable to the general population of Israel.

6.4.4. Discussion

Four articles were identified which explored risk factors for PHN in the general population. Three studies investigated evidence of a genetic susceptibility to PHN, and two case-control studies found some indication that alleles within the HLA region were associated with PHN. There was a single cohort study assessing various risk factors for PHN in the general population, which reported female gender, high SES, recent cancer treatment, HIV and

diabetes were associated with increased risk of PHN. However, three of the four studies had at least one pre-specified domain with a high risk of bias, limiting the value of the evidence.

From the perspective of zoster vaccination policy understanding the risk factors for PHN in the general population may be of greater value than information on risk factors for PHN among people already with zoster. Despite this, the majority of studies focusing on risk factors for PHN are nested within zoster cohorts. Exactly why risk factor studies using general population controls, rather than zoster controls, are far less common is not clear, however two reasons have been hypothesised here: 1) population-based studies may be more challenging to conduct compared to studies within zoster cohorts, as the comparison group is less easy to identify; 2) interpretation of population-based studies is more challenging as the risk of PHN is a combination of the risk of zoster, plus the risk of PHN, having developed zoster.

HLAs regulate immune responses against viruses therefore may be involved in the pathogenesis of PHN: a study among zoster patients did not find any association between the risk of acute zoster and the HLA region, which is in contrast to the studies assessed here focussing on PHN risk.[176] However, it should be emphasised that HLA alleles and haplotypes differ between populations; therefore the findings, if replicated in larger population-based studies, may only be generalizable to Japanese populations. Confirmation of findings from different ethnic populations would be important prior to considering if the HLA region is involved in the pathogenesis of PHN. Additionally the studies were very small and need to be substantiated in larger samples.

Weitzman *et al* uniquely contributed to the literature by conducting a large cohort study within the general population. However, the definition of PHN used in Weitzman's study was pain at one month following zoster, which may limit the applicability of their findings as the more widely used definition of PHN is pain three months or greater following zoster. Furthermore, the study may be subject to residual confounding by age, as age was included in the model as a categorical variable with very wide groupings.

This brief review of studies investigating risk factors for PHN in the general population has demonstrated that there is some evidence that genes in the HLA region may be involved in PHN susceptibility, specifically among people of Japanese ethnicity. It is however not known to what extent these genetic factors reflect the risk of zoster versus risk of PHN, which is a major limitation when assessing risk factors for PHN in general population studies. One study suggested that female gender, high SES, recent cancer treatment, HIV and diabetes were

associated with increased risk of PHN in the general population. Each study had some major weaknesses, limiting the quality of the evidence.

6.5. Chapter summary

Systematic review of risk factors for PHN among zoster patients

- Risk factors for PHN have been posited, but the evidence has never been systematically reviewed.
- Nineteen studies were selected for review, which assessed risk factors for PHN among adult zoster patients and reported age-adjusted effect estimates.
- The risk of PHN was significantly increased with clinical features of acute zoster including prodromal pain, severe acute pain, severe rash and ophthalmic involvement. Older age was significantly associated with PHN. Evidence for a difference in PHN risk by gender was conflicting, with considerable between-study heterogeneity. A proportion of studies reported an increased risk of PHN with severe immunosuppression (n=3/5 studies) and diabetes mellitus (n=1/4).
- The review has confirmed that a number of clinical features of acute zoster are associated with PHN. It identified a range of other possible risk factors for PHN, yet aside from age-associated risks, the evidence is currently limited. Larger studies with strict definitions of exposures and outcomes and control for confounding variables may elucidate some of the unknown risk factors for PHN.

Systematic review of risk factors for PHN in the general population

- Understanding risk factors for PHN within the general population may be particularly helpful in informing vaccination policy.
- Four studies were identified investigating risk factors for PHN in the general population, however all studies had some limitations, therefore the findings must be treated cautiously.
- Three case-control studies investigated genetic susceptibility to PHN; two found evidence that alleles in the HLA region, known to be involved in immunity, were associated with PHN in Japanese populations, whilst the third study found no evidence of family history of zoster being a risk factor for PHN. The final cohort study reported female gender, high SES, recent cancer treatment, HIV and diabetes were associated with increased risk of PHN.
- Interpreting results of these studies is more difficult, as the effect reflects both the risk of zoster plus the risk of PHN, once zoster developed. This difficulty in interpreting study results may explain why the majority of studies investigating risk factors for PHN remain in zoster cohorts.

Chapter 7: Quantification of risk factors for postherpetic neuralgia in a cohort of herpes zoster patients

7.1. Introduction

As demonstrated in the systematic review in chapter 6, knowledge of the risk factors for PHN is limited, with studies often being small and yielding inconsistent results. An understanding of PHN risk factors may be helpful in informing zoster vaccination policy, as patients at high risk of PHN could be specifically targeted. A large cohort study was therefore carried out to investigate risk factors for PHN among a cohort of zoster patients in CPRD. The findings from this study were written up as an article and the paper is currently accepted for publication at Neurology.

This chapter begins with the article, and is followed by the submitted appendices which were too detailed for the article. The appendices include detailed information of how age was modelled, how missing data were dealt with and a fuller investigation of gender as a risk factor for PHN.

7.2.1. Abstract

Objective: We aimed to investigate risk factors for postherpetic neuralgia, the neuropathic pain that commonly follows herpes zoster.

Methods: Using primary care data from the Clinical Practice Research Datalink, we fitted multivariable logistic regression models to investigate potential risk factors for postherpetic neuralgia (defined as pain ≥90 days after zoster, based on diagnostic and/or prescription codes), including demographic characteristics, co-morbidities, and characteristics of the acute zoster episode. We also assessed whether their effects were modified by antiviral use.

Results: Of 119,413 zoster patients, 6,956 (5.8%) developed postherpetic neuralgia. Postherpetic neuralgia risk rose steeply with age, most sharply between 50-79 years (adjusted odds ratio for a 10-year increase, 1.70, 99% confidence interval 1.63-1.78). Postherpetic neuralgia risk was higher in women (6.3% vs 5.1% in men: OR=1.19, 1.10-1.27); and those with severely immunosuppressive conditions, including leukaemia (13.7%: 2.07, 1.08-3.96) and lymphoma (12.7%: 2.45, 1.53-3.92); autoimmune conditions, including rheumatoid arthritis (9.1%: 1.20, 0.99-1.46); and other comorbidities including asthma and diabetes. Current and ex-smokers, as well as underweight and obese individuals were at increased risk of postherpetic neuralgia. Antiviral use was not associated with postherpetic neuralgia (OR=1.04, 0.97-1.11). However, the increased risk associated with severe immunosuppression appeared less pronounced in patients given antivirals.

Conclusions: Postherpetic neuralgia risk was increased for a number of patient characteristics and comorbidities, notably with age and among those with severe immunosuppression. As zoster vaccination is contraindicated for patients with severe immunosuppression, strategies to prevent zoster in these patients, which could include the new sub-unit zoster vaccine, are an increasing priority.

7.2.2. Introduction

Postherpetic neuralgia (PHN) is the commonest complication of herpes zoster[177] and may cause severe pain.[178] The lifetime incidence of zoster is 30% and an estimated 12·5% of zoster patients aged ≥50 years develop PHN.[23] Symptoms can persist for months or years, often profoundly affecting a patient's quality of life.[179] There are no known effective disease-modifying therapies for PHN. Treatments instead target symptom control, yet are often inadequate at relieving pain and are ineffective in almost half of PHN patients.[27,33,180]

To date, observational and trial data have provided inconsistent evidence that administering antivirals at rash onset reduces PHN risk.[31] These trials also tend to exclude immunosuppressed patients, such that the efficacy of antivirals to prevent PHN in this patient group is greatly under-researched. The only proven and available intervention to reduce PHN risk is through VZV vaccination.[19] However, the high-cost of the vaccine means many countries limit its coverage. A recent review demonstrates our incomplete understanding of PHN risk factors;[181] except for age, evidence is conflicting and studies are often underpowered to detect associations. Considering the dearth of effective treatment options for PHN, identifying PHN risk factors to inform zoster vaccination policy could have important public health benefits.[4]

This paper aims to quantify risk factors for PHN in a large prospective study among zoster patients. It also investigates whether antivirals modify the effect of these risk factors on PHN.

7.2.3. Methods

7.2.3.1. Study design and setting

We conducted a study among zoster patients using prospectively collected data from the Clinical Practice Research Datalink (CPRD), a large routinely collected UK database of anonymised primary care records. CPRD is broadly representative of UK patient and practice characteristics.[85] 60% of CPRD patients had data available in the Hospital Episode Statistics (HES) database (Version 9), a linked database of hospital attendances in England from 1997. Clinical diagnoses are coded in CPRD with Read codes and in HES with ICD-10 codes.[85]

7.2.3.2. Study population

The study cohort included patients with first ever zoster (identified previously[182]), followed-up to determine who develops PHN. Briefly, these patients were diagnosed with zoster between 01/01/2000 and 31/12/2011 in CPRD (Read code for zoster and >12 months follow-up in CPRD before zoster diagnosis [to ensure the code represented incident zoster]) or HES (ICD-10 code for zoster in the primary diagnosis field of any episode). The zoster vaccine was introduced into the UK in 2013, therefore this was an unvaccinated population.

7.2.3.3. Definition of PHN

Our underlying definition of PHN was pain persisting ≥90 days following zoster diagnosis.[27] The primary definition of PHN included patients classified as having diagnosed, probable or possible PHN, based on a validated algorithm of PHN within a US administrative database utilising diagnosis codes and prescription data.[102] See Table 1 for full definition.

Exclusions

As anticonvulsant prescriptions were part of our PHN algorithm (Table 1), patients with other indications for anticonvulsants (e.g. epilepsy) recorded pre-zoster were excluded. We also excluded patients without 365 days follow-up after zoster diagnosis; we could not know whether individuals censored before 365 days without PHN met our PHN definition, which used data to 365 days.

7.2.3.4. Risk factors of interest

Demographic risk factors included age at zoster, gender and socioeconomic status. Comorbidities included severely immunosuppressive conditions, specifically a recent history (<2 years before zoster diagnosis) of leukaemia or lymphoma, or any history of HIV, hematopoietic stem cell transplantation, myeloma or 'other unspecified cellular immune deficiencies' (e.g. pancytopenia), or ≥14-day course of high-dose (≥20 mg/day) oral corticosteroids, or exposure to other immunosuppressive therapies, in the month prior to zoster diagnosis. Other comorbidities included autoimmune conditions (systemic lupus erythematosis (SLE), rheumatoid arthritis (RA), inflammatory bowel disease (IBD)), diabetes, chronic obstructive pulmonary disease (COPD), asthma, chronic kidney disease (CKD), personality disorder, recent depression and recent cancer. Other characteristics included

smoking, BMI, site of acute zoster rash and antivirals given within 7 days of zoster diagnosis (appendix, section e-I).

7.2.3.5. Statistical analysis

Crude and age-adjusted odds ratios (ORs) were calculated to estimate the strength of association of each potential risk factor with PHN at 90 days (defined above), using logistic regression. The age-PHN association was non-linear, therefore age was modelled as a 5-knot restricted cubic spline. To numerically summarise the effect of non-linear age on PHN risk we also fitted piecewise linear models (appendix, section e-II).

Multivariable analyses using logistic regression were carried out on patients with complete data for all variables. All variables were included in the final model. Two models were built, first excluding then including immunosuppressive therapies, to assess whether some of the overall effects of diseases were mediated by their treatments.

Antivirals given at zoster may modify the risk of PHN. Antivirals are given to approximately 60% of patients with zoster in CPRD.[183] We calculated stratum-specific ORs for each variable in the multivariable model by whether patients received antivirals. Patients potentially receiving antivirals in hospital were excluded from this analysis (figure 1). In a *post-hoc* analysis we also calculated the adjusted OR for the effect of antivirals on PHN risk among patients with immunosuppression using logistic regression.

Finally, a potentially effect-modifying role of age was investigated by computing stratum-specific ORs for each variable in the multivariable model by age groups “<70 years" and "≥70 years” as well as “<60 years" and "≥60 years” (age groups chosen to reflect different vaccination ages, e.g. ≤60 years in the US[38] and 70, 78 or 79 years[184] in the UK).

General practice was included in all models as a random effect to account for clustering, as data might be correlated within practices.

Sensitivity analyses and bias assessments

We repeated the main risk factor analysis: 1) for PHN at 30 days following zoster; 2) restricting PHN cases to diagnosed PHN only (Table 1); 3) excluding possible misdiagnosed herpes simplex patients (appendix, section e-I). We tested for healthcare utilization bias by assessing the

association between PHN and hypothyroidism (a chronic condition requiring high-level health-care use,[185] not associated with PHN) and calculated mean yearly consultation rate pre-zoster to confirm hypothyroidism patients had the same opportunity for PHN diagnosis (i.e. via GP contact). We used multiple imputation by chained equations[127] as an alternative approach to account for missing data (9% of patients had missing data for BMI or smoking) (appendix, section e-III).

Bias may be introduced from excluding patients <365 days follow-up post-zoster if those included had a different association between our risk factors and PHN, compared to those excluded. We repeated the main analysis, restricting our outcome definition to PHN identified up to 120 and 180 days after zoster; the follow-up requirements are less, thus any selection biases due to excluding patients with insufficient follow-up is reduced.

7.2.3.6. Standard Protocol Approvals, Registrations, and Patient Consents

The study was approved by ISAC [application no.11028] and the London School of Hygiene and Tropical Medicine [application no.5930].

7.2.4. Results

Of 144,959 patients with zoster, 119,413 were eligible for inclusion (appendix, Figure e-1). Almost 60% of the sample was female (Table 2) and the median age was 61 years (IQR:48-72, range:18-101). In total, 6,956 zoster patients (5.8%) developed PHN.

The risk of PHN rose with age (appendix, Figure e-2) and the association was non-linear (P<0.001, appendix Figure e-3). Patients 50-79 years had the steepest increased risk of PHN (Table 3); a 10-year increase in age within this age-band was associated with 70% increased risk of PHN (adjusted OR (adjOR):1.70, 99%CI:1.63-1.78), whereas the effect of a 10-year increase in age was attenuated above age 80 years (adjOR:1.10, 99%CI:0.94-1.28). Women were more likely to develop PHN than men, an association which remained after adjustment (adjOR:1.19, 99%CI:1.10-1.27) (Table 3).

Conditions and therapies causing severe immunosuppression were strong risk factors for PHN (Table 2 and 3). Patients with leukaemia or lymphoma in the previous two years, myeloma or other unspecified cellular immune deficiencies ever, or recently taking high-dose oral corticosteroids had over twice the risk of developing PHN, compared to unaffected patients.

For HIV, the point estimate was also large, however only 6 of 99 HIV patients developed PHN, hence the evidence for an association was weak (adjOR:2.17, 99%CI:0.64-7.37).

Of the autoimmune conditions, SLE was most strongly associated with PHN (adjOR:1.76, 99%CI:1.04-2.98) (Table 2 and 3). RA and IBD were also associated with a higher PHN risk (9.1% and 7.5% respectively) with some evidence they were associated with between 10-20% increased risk of PHN after adjustment for confounders; the effects of these two conditions were less pronounced after adjusting for immunosuppressive drugs.

Of the other comorbidities assessed (Table 2 and 3), COPD was associated with a 53% increased risk (PHN risk 13.2%; adjOR:1.53, 99%CI:1.35-1.72) and recent depression a 40% increased risk (PHN risk 7.0%; adjOR:1.40, 99%CI:1.20-1.62). Asthma and type 2 diabetes were associated with 20% increased risk of PHN. After fully adjusting for confounders, personality disorder, CKD or recent cancer diagnosis were not associated with PHN.

The overall risk of PHN among current smokers was lower than the study sample overall (5.4% vs 5.8%), however after adjusting for age, there was around 30% increased risk of PHN in current smokers (adjOR:1.27, 99%CI:1.15-1.39) (Table 2). Being underweight or obese was also associated with PHN. PHN was more prevalent in patients with non-truncal zoster (Table 2 and 3).

The effects of the risk factors on PHN were broadly similar between those given and not given antivirals, except for individuals with leukaemia (P-value for interaction 0.045), SLE (0.026), COPD (0.043) and smoking (0.002); point estimates for their effect on PHN appeared higher in those not given antivirals (Figure 1 and appendix Table e-8). *Post-hoc* analysis found no evidence that antivirals reduced the risk of PHN in patients with immunosuppression (appendix, section e-V).

The effect of COPD (P-value for interaction 0.006), diabetes (0.004), currently smoking (0.006), or being obese (0.037) were slightly stronger in patients <70 years (appendix, Table e-1); the effect of asthma (0.068), CKD (0.018), diabetes (0.018) and being underweight or obese were slightly stronger in patients <60 years (0.031) (appendix, Table e-2). However, no clear patterns were observed.

Sensitivity analyses

We re-ran the main analysis varying the PHN definitions. Most confidence intervals included the point estimate from the main analysis (appendix, Table e-3), except for: PHN at 30 days was associated with antiviral use (adjOR:1.12, 99%CI:1.06-1.18), yet less strongly associated with ophthalmic zoster (adjOR:1.72, 99%CI:1.56-1.91); restricting the outcome to diagnosed PHN only, the effect of ophthalmic zoster (adjOR:2.67, 99%CI:2.24-3.19) and a 10-year increase in age between 50-79 years (adjOR:2.08, 99%CI:1.92-2.24) became stronger and the effect of female gender disappeared (adjOR:1.00, 99%CI:0.89-1.14).

We explored in *post-hoc* analysis this loss of an association with female gender (using the primary PHN definition). The effect of female gender on PHN was driven by cases of PHN defined using tricyclic antidepressant use, yet we found evidence suggesting prescribing practices for PHN differ by gender (appendix, section e-IV).

Of 7,416 patients with hypothyroidism, 599 (8.1%) developed PHN. The fully adjusted OR between hypothyroidism and PHN indicated no association (adjOR:1.01, 99%CI:0.90-1.14, adjusted for variables in Table 3 Model 2); furthermore, mean yearly consultation rates among patients with our risk factors of interest were very variable (appendix, Table e-6), showing no consistent pattern with PHN risk.

Accounting for missing BMI and smoking data using multiple imputation made no difference to the results (appendix, Table e-7). Restricting to shorter follow-up periods (specifically 120 and 180 days) also had no major effect on the results (appendix, Figure e-4).

7.2.5. Discussion

This study shows older age and severe immunosuppression, such as recently having lymphoma or leukaemia, are the strongest risk factors for PHN among zoster patients. Although immunosuppressed patients are not currently eligible for vaccination, promising research on a new sub-unit zoster vaccine (HZ/su) may enable vaccination within this group.[47] Other risk factors included: autoimmune conditions (RA, SLE and IBD), COPD, depression, diabetes, asthma, lower socioeconomic status, smoking, being under- or overweight and non-truncal zoster. Antivirals given at zoster were not associated with PHN risk overall, but there was some weak evidence that their use mitigated the increased risks associated with leukaemia, SLE, COPD and smoking.

This study addresses an absence in the literature of well-powered studies assessing PHN risk factors.[181] The study benefits from: being the largest study addressing this question; being population-based; using a dataset broadly representative of the UK;[85] tightly accounting for confounding by age; and using a more precise definition of PHN than earlier studies using routinely collected data.

Despite its strengths, this study has some limitations. Although we attempted to reduce misclassification of PHN by basing our definition on a validated method for administrative data,[102] PHN incidence is lower than previous studies (5.8% versus 7.2% in an Icelandic study with active follow-up of similar aged zoster cases[186]). The reported prevalence of PHN varies hugely across studies. We used a 90 (rather than 30) day definition and included patients <50 years old, which may explain the relatively low PHN prevalence. However, some PHN diagnoses could have been missed. Unidentified cases are likely those with mild pain, who used over-the-counter medications for initial pain relief or (if GP-prescribed treatments were ineffective) for follow-on pain relief. These findings are therefore likely to be generalizable to patients with severe PHN. Another explanation for the low prevalence may be that some immunocompromised patients are treated exclusively in secondary care; however, this is likely to be a few cases only, because PHN is largely treated in primary care.

Certain clinical features of zoster are accepted PHN risk factors, including prodromal pain and increased rash severity.[181] In CPRD, these data are unavailable. These features may lie on the causal pathway or be mediators between our exposures and PHN. For example, leukaemia patients may experience greater viral load, which manifests as a severe rash and increase PHN risk. It would be inappropriate to control for rash severity, as we want the total effect of leukaemia on PHN; lacking data on these clinical features is therefore unlikely to limit our findings.

In numerous studies increasing age is associated with a sharp increase in PHN risk.[23,187] Our study identified a non-linear age effect; PHN risk increased steeply between 50-79 years and attenuated after age 80. A Dutch cohort study among 837 zoster patients[13] suggested PHN incidence continues to increase in individuals >80 years; however PHN was defined as analgesic prescription three months post-zoster, potentially causing misclassification, particularly among older individuals. Other studies report PHN risk lessening around 80 years.[26,100,188] Our observed effect may arise from under-ascertainment of PHN in patients >80 years due to: frailty preventing GP attendance; or PHN-associated pain being superseded by other comorbidities.

Previous studies have not identified depression as a risk factor for PHN,[189-192] unlike our study. We acknowledge our result may be driven by patients requiring tricyclic antidepressants for depression, and being misclassified as PHN cases; when restricting PHN cases to diagnosed PHN only, the association with depression disappeared (adjOR:1.12, 99%CI:0.84-1.49). However, the wide confidence intervals suggest there may have been insufficient power to detect an effect.

The study found no evidence that antivirals protected against PHN. This is unlikely to be attributed to inadequate dosing, as 93% of treated patients received at least the recommended minimum antiviral dose. However, other limitations could explain this null finding. In primary care, patients with severe zoster are recommended to receive antivirals, yet are also more likely to develop PHN. This may introduce confounding by indication and mask a protective effect. Also, trial data has assessed the efficacy of antivirals administered within 72 hours of rash onset.[31] Although 97.5% of patients were prescribed antivirals on the day of zoster diagnosis, zoster treatment initiation may occur >72 hours after rash onset, when the effect of antivirals is unproven. Although data on time from actual rash onset to presentation at general practitioners is not available in this data set, two previous UK studies suggest 50-65% of patients present within 72 hours,[193,194] leaving a number of patients treated after 72 hours from rash onset.

Our recent systematic review of PHN risk factors concluded there was no consensus regarding immunosuppression as a risk factor for PHN.[181] The present study demonstrates that immunosuppression is associated with greater PHN risk and the study had sufficient power to assess the effect of specific immunosuppressive conditions and therapies on PHN risk. Our study is also novel in identifying autoimmune conditions as PHN risk factors; autoimmune conditions had scarcely been assessed previously, though SLE was associated with over two-fold increased risk of PHN in a large Taiwanese cohort study.[195]

Disentangling the role of diseases and their drug treatments on the PHN risk is challenging. There was little evidence that the increased risks associated with severely immunosuppressive conditions were mediated by immunosuppressive drugs. However, treatment such as chemotherapy, given in secondary care, is not captured in CPRD and probably explains at least part of the increased risk. The effects of IBD and RA on PHN were less pronounced after adjusting for immunosuppressive treatments, suggesting that the association is driven predominantly by exposure to these drugs. By contrast, the effect of SLE did not appear to be

mediated by immunosuppressive therapies, although CRPD lacks reliable data on newer biological therapies.

Establishing the role of severe immunosuppression and autoimmune conditions on PHN risk may help shed light on the underlying pathophysiological mechanisms that lead to PHN, which are poorly understood. Two key aetiological hypotheses are: that PHN is caused by a persistence of varicella-zoster virus following zoster; or by increased neuronal excitability and alteration of pain perception.[33,34] Our finding of a strong association between immunosuppression and PHN risk seems to support the former hypothesis; lower cell-mediated immunity may lead to higher levels of virus during acute infection and thus an increased risk of PHN.

Cost-effectiveness studies are needed to determine the value in vaccinating patients with identified risk factors for PHN against zoster. Those of older age and with severe immunosuppression were at the highest risk of PHN. Strategies to prevent zoster in patients with severe immunosuppression are an increasing priority as these patients are not currently eligible for zoster vaccination, although the new development of a subunit vaccine provides a promising alternative.[47]

Table 1: Postherpetic neuralgia classifications. The primary analysis included diagnosed, probable and possible postherpetic neuralgia patients

PHN classification	
Diagnosed PHN	PHN code* (90-365 days post-zoster)
Probable PHN	Zoster code and prescription consistent with PHN• on same day (90-365 days post-zoster)
	Non-specific neuralgia code (90-365 days post-zoster)
	NEW anticonvulsant or capsaicin cream or lidocaine patch prescription (90-180 days post-zoster)
	NEW tricyclic antidepressants 90-180 days post-zoster with no other indication on the day of the prescription, plus evidence of the drug being prescribed for zoster or PHN previously†
Possible PHN	**NEW** tricyclic antidepressants 90-180 days post-zoster with no other indication on the day of the prescription
	NEW strong painkiller 90-180 days following zoster with no other indication on the day of the prescription, plus evidence of the drug being prescribed for zoster or PHN previously†
	Non-specific neuropathic pain code (90-365 days post-zoster)

PHN: Postherpetic neuralgia.
*Read code for PHN in CPRD or (for those with linked data) an ICD10 PHN code in the primary diagnosis field within any episode of linked HES.
•Prescriptions included anticonvulsants, tricyclic antidepressants, capsaicin cream or lidocaine patch.
NEW prescriptions were defined as no previous prescriptions of the same medication type 12 months to two weeks prior to zoster, to increase the likelihood of the medication being prescribed for PHN (medications may have been prescribed for pain management two weeks pre-zoster, if zoster initially presented without a rash).
†Here, previously is defined as a prescription 0-89 days following zoster.
Medications indicative of zoster were only considered in the 90-180 day period after zoster diagnosis (rather than 90-365 days) to reduce the chance of misclassifying other reasons for medication use as PHN.

Table 2: Baseline characteristics of 119413 eligible zoster cases and the proportion developing PHN

	Total cohort, n (%)	No. with PHN, n (%)

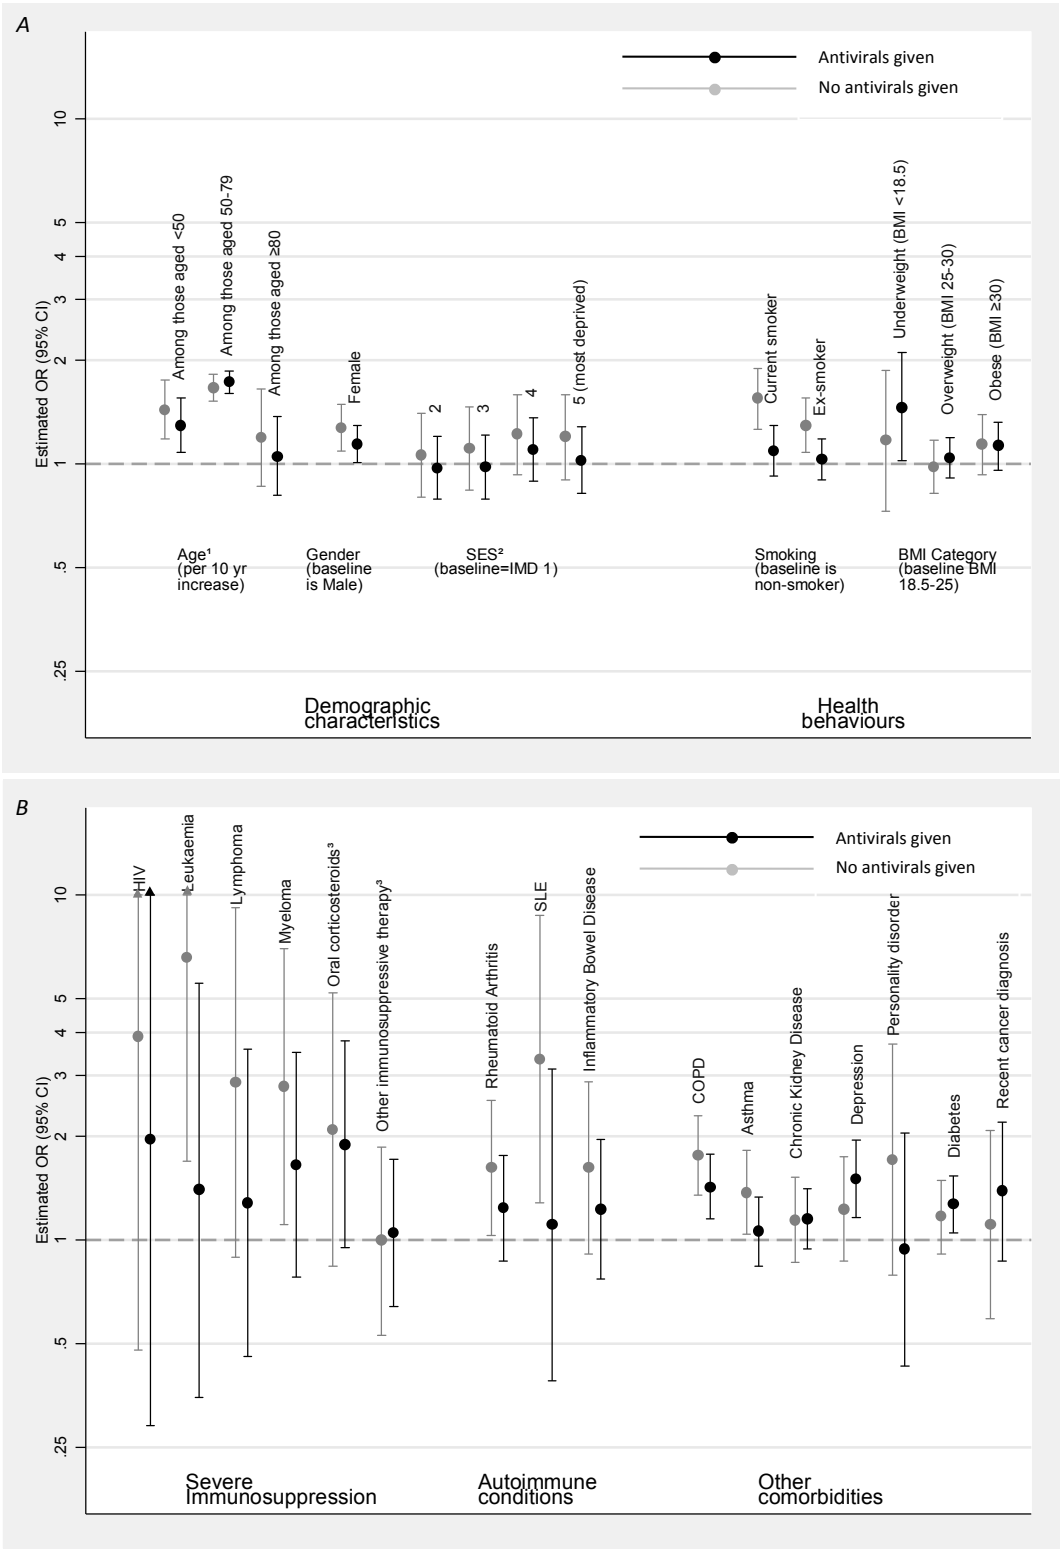
†Adjusted for age, gender, socioeconomic status, HIV, leukaemia, lymphoma, myeloma, hematopoietic stem cell transplantation, other unspecified cellular immune deficiencies, rheumatoid arthritis, systemic lupus erythematosis, inflammatory bowel disease, COPD, asthma, chronic kidney disease, depression, personality disorder, diabetes, recent cancer diagnosis, smoking, BMI category, site of zoster and antivirals. [1]ORs estimate the effect of a 10-year increase in age on PHN derived, in age groups <50, 50-79 and ≥80, from piecewise linear splines. [2]Measured by Index of Multiple deprivation score. [3]Includes patients currently taking a 14 day course of immunosuppressive medications, or terminating a 14 day course of immunosuppressive medications less than one month prior to the zoster diagnosis. Oral corticosteroid prescriptions were required to be high dose (≥20mg per day). There was no evidence of collinearity between variables (indicated by a 20% increase in standard errors in the fully, versus age-adjusted, model for each risk

Figure 1 A and B: Adjusted† associations between postherpetic neuralgia and A) demographic risk factors and health behaviours and B) comorbidities, stratified by whether a patient received antivirals during acute zoster. Analyses are restricted to 69,661 patients for whom antiviral status was most likely to be available.* Full results can be found in appendix, Table e-8.



†Adjusted for age, gender, socioeconomic status (SES), HIV, leukaemia, lymphoma, myeloma, immunosuppressive therapies, rheumatoid arthritis, systemic lupus erythematosis, inflammatory bowel disease, COPD, asthma, chronic kidney disease, depression, personality disorder, diabetes, recent cancer diagnosis, smoking and BMI category. Please note hematopoietic stem cell transplantation and other unspecified cellular immune deficiencies were excluded due to too few numbers. *Patients excluded were those with zoster diagnosed in HES or having a HES visit for zoster 7 days after diagnosis (n=494), patients who were not HES-linked (n=45,418) and patients with non-truncal zoster (n= 3,840), as their antiviral use may not be recorded in CPRD.[1]ORs estimate the effect of a 10-year increase in age on PHN derived, in age groups <50, 50-79 and ≥80, from piecewise linear splines. [2]Measured by Index of Multiple deprivation score (IMD1=least deprived, IMD5=most deprived). [3]Includes patients currently taking a 14 day course of immunosuppressive medications, or terminating a 14 day course of immunosuppressive medications less than one month prior to the zoster diagnosis. Oral corticosteroid prescriptions were required to be high dose (≥20mg per day). Interaction terms between antiviral use and other risk factors were added to the model one at a time.

7.3. Accepted appendices

e-I: Further details on definitions of risk factors

Aside from the discussion below about possible misdiagnosis of herpes simplex patients as zoster patients, this section (e-I) of the appendices repeats information written in chapter 3, "Data sources and variable definitions", therefore has been placed in the thesis appendices (appendix IV).

Possible misdiagnosis of herpes simplex as herpes zoster

Of the 119,413 cohort, 1586 (1.6%) patients had a further zoster code 90-365 days after their first zoster. Of these 215 (13.6%) had a PHN medication or a PHN diagnostic code, and in the main analysis these were categorised as PHN. However, the other 1371 patients had a zoster code without medications or codes suggesting PHN. There were three possible explanations for these patients. The first is that they were recurrent zoster; however this is very rare in immunocompetent patients, who made up 96% of the group. The second is that these are poorly coded PHN patients, however it seems unlikely that no PHN prescriptions would be given. The third, and perhaps most plausible explanation is that these patients were misdiagnosed herpes simplex cases. Herpes simplex is known to recur more frequently than zoster and can, albeit rarely, present with dermatomal distribution similar to herpes zoster. [196] Further to this, half of the patients were prescribed an antiviral at their later zoster diagnosis, which may further indicate misdiagnosis of herpes simplex. Therefore as a sensitivity analysis we excluded all 1586 patients with a further zoster code following first zoster diagnosis.

e-II: Modelling age

a) Using restricted cubic splines to adjust for age

There was very good evidence that the relationship between PHN and age at zoster diagnosis was not linear (test for departure from linear trend $P<0.001$); in other words there was no evidence of a constant increase in the log odds of PHN per unit increase in age.

Categorizing age into groups was considered but not pursued as this may lead to loss of information. Splitting age into categories would assume there is a single exposure effect within that category; considering age is such a strong risk factor for PHN this may be an unrealistic assumption. Further to that, cut-points are often arbitrarily chosen potentially heavily influencing the apparent shape of the age-PHN relationship.[197] Allowing for a non-linear relationship would improve our understanding of the relationship between age and PHN,

reduce the possibility of residual confounding by age when including it as a confounder and improve the model from a statistical viewpoint.

We therefore utilised restricted cubic splines to make better use of within category information and allow for non-linearity. Splines are a type of smoothing function which provide a continuous curve rather than a step function. Cubic splines are one type of spline where the effect measure is regressed on a cubic function of exposure (here, age), across several different regions or categories of exposure and spanning the entire range of exposure. So cubic splines consist of piecewise cubic polynomials (in other words curves with up to 2 turning points) between specified "knots". The "restricted" means the relationships will be linear before the first knot and after the last knot. A single smooth curve across these regions is then produced.

As there was no obvious biological rationale for where to place the knots, they were placed at equal percentiles of age. The number of knots was chosen by assessing the Akaike information criterion (AIC) when 3 to 7 knots were included: the AIC criterion is a measure of the relative quality of a model given a set of data and thus provides a method to select the most appropriate model. AIC rewards goodness of fit of a model but includes a penalty for increasing number of parameters; this therefore discourages over-fitting (including more parameters will almost always improve the fit of the model). The model with the minimum AIC is preferred. Here, the AIC reduced from 49825 to 49758 when modelling it as a 3-knot and 5-knot respectively. The reduction in AIC beyond 5 knots was marginal (6 knots: 49753, 7 knots: 49728), therefore 5 knots were chosen (with knots at 26, 49, 61, 71, 84 years).

b) Using piecewise linear splines to estimate the effect of age on PHN

Restricted cubic splines provide a smooth curve of the age-PHN relationship and impose few constraints on that curve; however, they have the drawback of not providing interpretable parameters. Linear splines were used to estimate the relationship between age and PHN as a piecewise linear function, in other words a function composed of linear (straight line) segments between the specified knots. The points (knots) at which the linear segments join were determined by first, looking at the restricted cubic spline graph to assess where the effect of age on PHN appeared to alter. We then fitted piecewise linear models across various possible threshold values and used the one giving the lowest AIC. The knots were at 50 and 80 years.

e-III: Dealing with missing data

We used multiple imputation to account for missing data. Missing data were present for BMI and smoking. In total, 91% percent of patients had complete data for all variables. To maximise the use of the data while properly incorporating the extra uncertainty arising due to missing data, multiple imputation by chained equations [127] was used to impute missing values for BMI and smoking from multinomial models. The imputation model included all covariates from the main outcome model (Model 2 in table 2), with age included as a 5-knot restricted cubic spline. We also included extra comorbidities, identified using medical Read codes, to look for additional markers of BMI or smoking related diseases. These included: stroke, peripheral artery disease, angina (stable and unstable), acute coronary syndrome, congestive heart failure, myocardial infarction, hypertension and alcoholic liver disease (including portal hypertension) and pancreatitis. Five imputed datasets were created and combined for analysis. Distributions of imputed values were visually checked for comparability with the observed data. This was not done as the primary approach due to possible violation of the "missing at random" assumption for BMI and smoking.

e-IV: Investigating gender as a risk factor for PHN

In a sensitivity analysis which restricted the PHN definition to diagnosed PHN only (that is, patients with a Read code for PHN 90-365 days following zoster), female gender was no longer associated with an increased risk of PHN (table e-2, sensitivity analysis 2). We carried out some post-hoc analysis to investigate this further.

Gender distribution by PHN classification (diagnosed, probable and possible PHN)

The proportion of females among those with diagnosed, probable and possible PHN was 61.8%, 65.4%, 66.4% respectively. The effects of gender on PHN risk showed some variation across PHN classifications (see Table e-3); gender was not associated with diagnosed PHN, whilst females appeared to be at increased risk of probable and possible PHN. The association between gender and PHN according to the exact source of evidence for PHN was calculated (see table e-6); PHN defined from prescription of tricyclic antidepressants was driving the increased risk of probable and possible PHN in females (see table e-4, analysis A).

Three hypotheses were suggested and explored to explain this pattern:

c) *Patients with depression were being misclassified as PHN cases:* Of particular concern was that PHN cases defined from tricyclic antidepressant use were actually patients with depression, a condition widely known to be more common in females. To explore whether there may be systematic misclassification of PHN, the effects of gender on PHN risk were stratified by history of mental health problems ever in CPRD prior to zoster. These mental health problems included symptoms or diagnoses suggesting depression, anxiety, bipolar, or suicidal ideation. In both strata there appeared to be an increased risk of tricyclic antidepressant-defined PHN, suggesting the association between PHN and gender isn't driven entirely by previous mental health problems (see table e-4, analysis B and C). As a secondary check, patients with depression (using depression diagnosis and depression symptom codes) in the year prior to zoster or the year following zoster were excluded; there was still an increased risk of PHN defined by tricyclic antidepressant use among females (see table e-6; analysis D).

d) *Females with PHN are more likely to be prescribed medications than males with PHN:* Among 2156 patients with "diagnosed PHN", 33% (701/2156) did not receive any PHN medications 90-180 days following zoster. It was hypothesised that females may be more likely to receive treatment when visiting their GP; however, there was little difference in the proportion of male and females prescribed medications 90-180 days following zoster (69.8% vs 66.1% respectively, chi-squared P-value=0.07).

e) *Females with PHN are more likely to receive a tricyclic antidepressant than males with PHN:* Among patients with diagnosed PHN who received treatment 90-180 days following zoster (n=1455), females were more likely to receive tricyclic antidepressants in the 90-180 day period than males; 43.6% (384/880) females received a tricyclic, compared to 34.8% (200/575) of males (chi² P-Value=0.001). This suggests GPs may have different prescribing practices for males and females, which may explain why PHN defined through tricyclic antidepressant use is associated with gender.

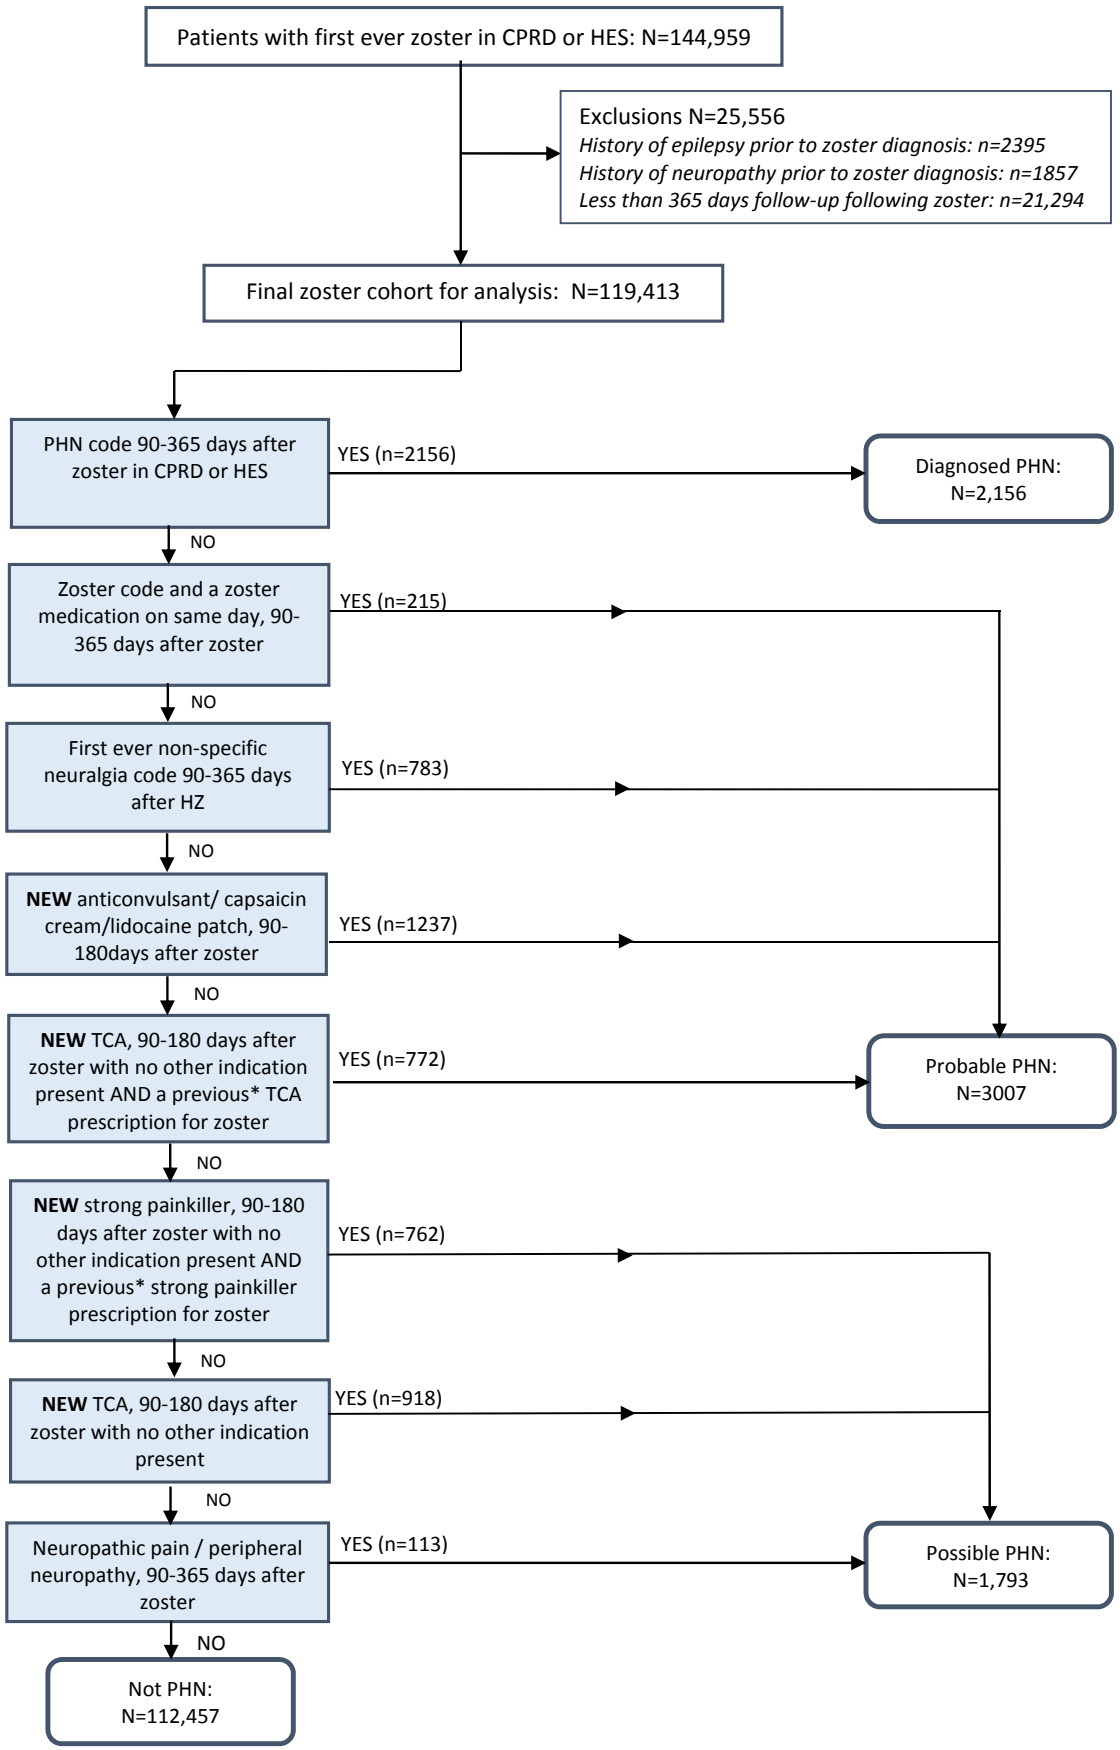
We therefore concluded that the association between gender and probable and possible PHN reflects different prescribing practices; specifically that female PHN patients are more likely to be given a tricyclic antidepressant compared to male PHN patients.

e-V: Effect of antivirals in patients with immunosuppression

Post-hoc analysis explored whether antivirals reduced the risk of PHN in patients with immunosuppression. Among patients with *any* severely immunosuppressive condition (grouped due to small numbers; n=1614), 8.3% of those given antivirals developed PHN (86/1,043), compared to 10.9% not given antivirals (62/571); however this was compatible with chance variation (OR for the effect antiviral use on PHN risk, among those with severe immunosuppression: 0.73, 99%CI:0.45-1.18, adjusted for variables in Table 2 Model 2).

Using antivirals to prevent PHN in patients with immunosuppression is under-researched; many trials exclude these patients.[31] In this *post-hoc* analysis, the rate of PHN among severely immunosuppressed patients given antivirals was lower, than those not given antivirals, but the confidence interval around the OR was wide and included one, reflecting the small numbers available. Given that *a priori* we assumed antiviral use would be associated with greater risk of PHN (due to confounding by indication; patients with severe zoster are more likely to develop PHN and receive antivirals) a lower risk of PHN in this group, albeit non-significant, suggests antiviral effectiveness in patients with severe immunosuppression should be investigated further. Capture of antiviral therapy among the more severely immunosuppressed patients may be poor, as patients could be immediately referred for intravenous antiviral therapy; therefore, differential misclassification of antiviral exposure may be driving the higher risk of PHN in the “no antivirals” group.

Figure e-1: Flow diagram describing the identification of diagnosed, probable and possible postherpetic neuralgia

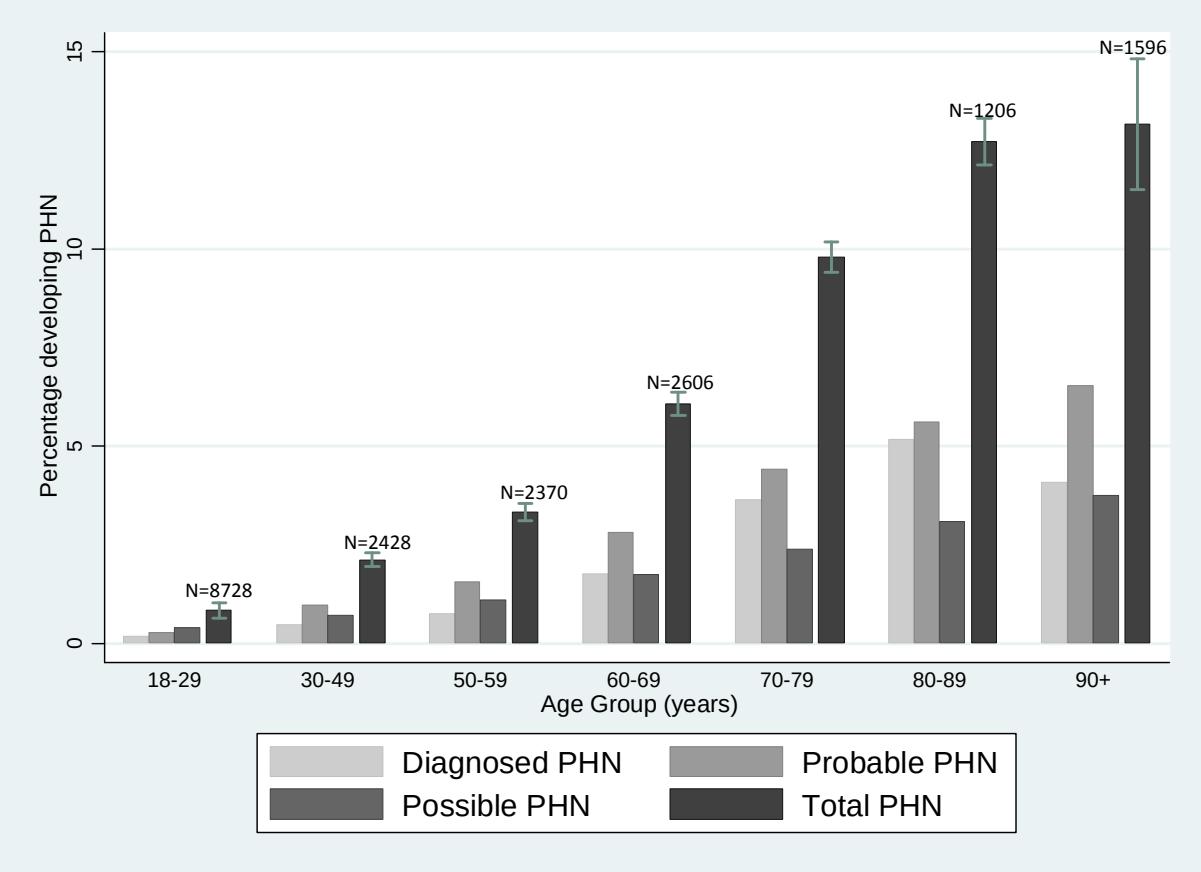


Notes

TCA: tricyclic antidepressants. **NEW** medications defined as no previous prescription of the same drug class 12 months to two weeks prior to zoster diagnosis.

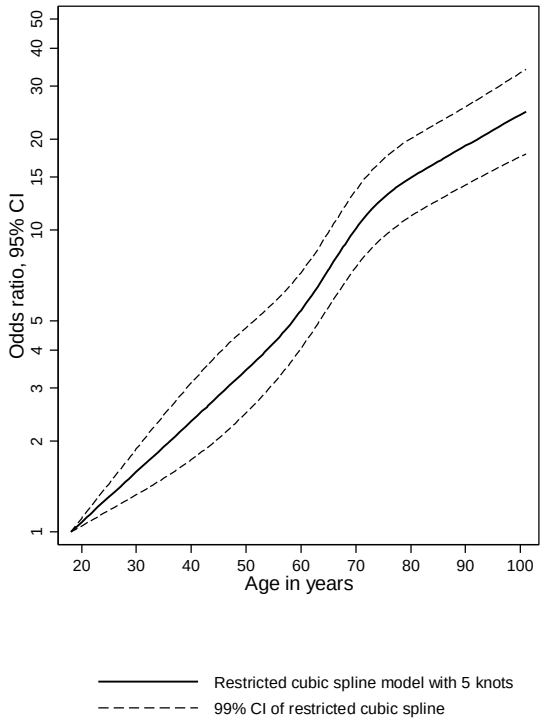
*A previous prescription for zoster is defined as zoster/PHN code and prescription (TCA or strong painkiller) on the same day, 0-89 days after zoster

Figure e-2: Prevalence of postherpetic neuralgia in the cohort of 119,413 zoster patients, by age group and postherpetic neuralgia classification (diagnosed, probable or possible postherpetic neuralgia)



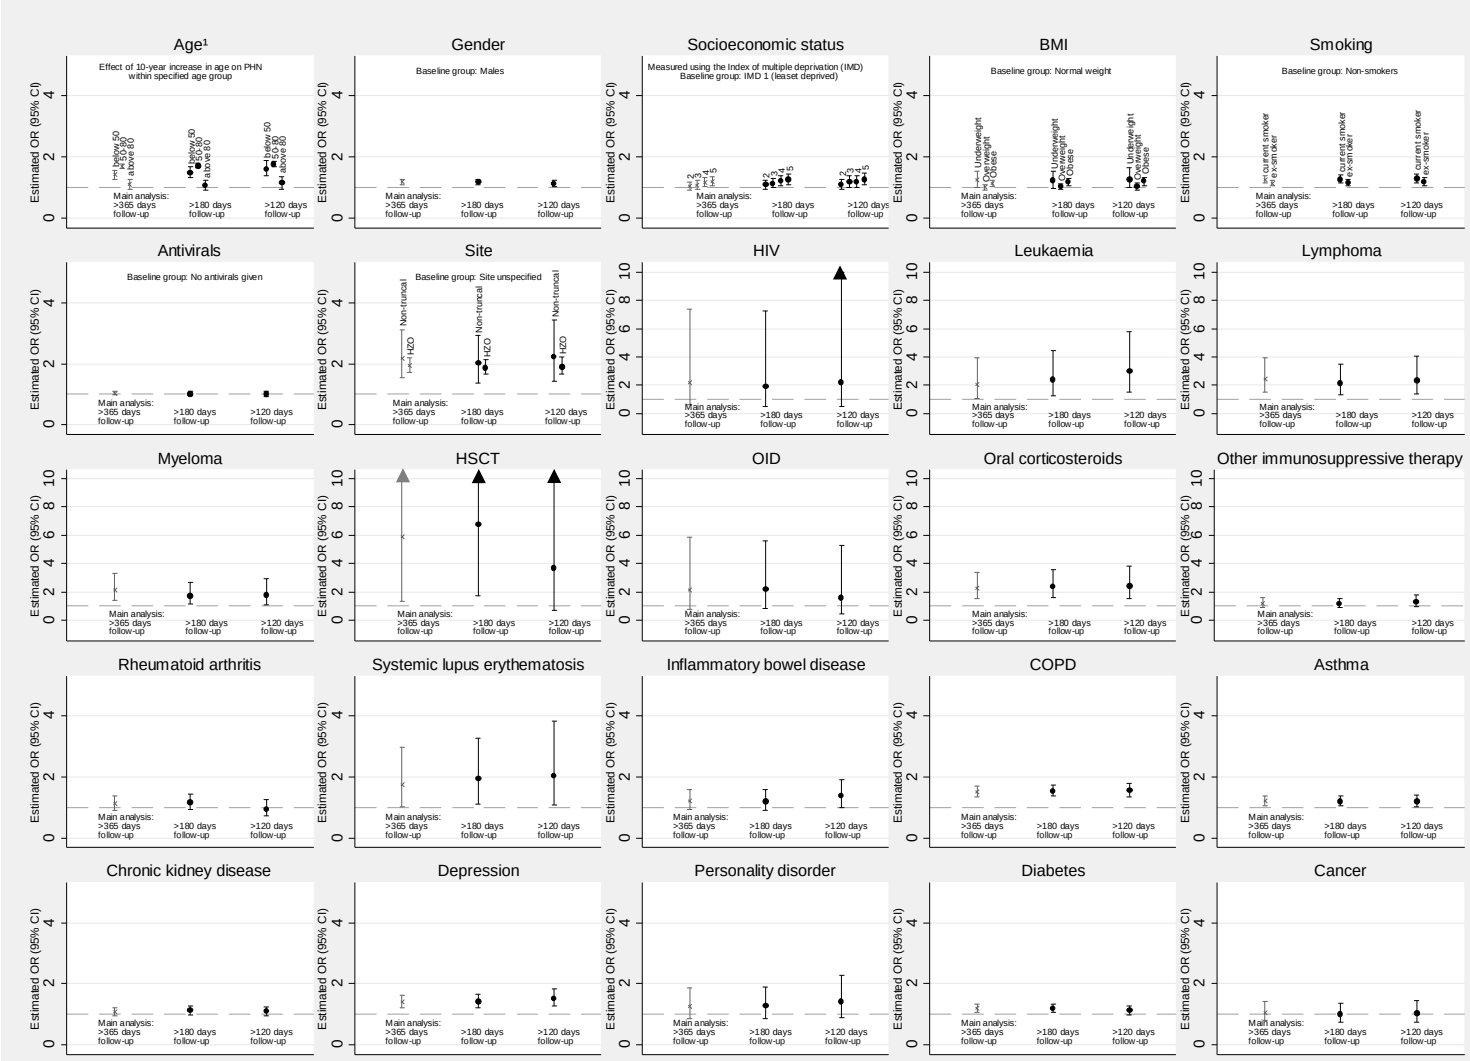
PHN: Postherpetic neuralgia. See Table 1 for description of PHN classifications.

Figure e-3: Association between postherpetic neuralgia and age at zoster diagnosis, modelled using a 5-knot restricted cubic spline



The 5-knot restricted cubic spline model is centred at 18 years. Knots were placed at equal percentiles of the data, with Akaike information criterion used to select optimal knots. Curves estimated were adjusted for gender, socioeconomic status, HIV, leukaemia, lymphoma, myeloma, hematopoietic stem cell transplantation other unspecified cellular immune deficiencies, immunosuppressive therapies, rheumatoid arthritis, systemic lupus erythematosis, inflammatory bowel disease, COPD, asthma, chronic kidney disease, depression, personality disorder, diabetes, recent cancer diagnosis, smoking, BMI category, antiviral use and site of zoster (as in Model 2 from table 2). The data are shown on a natural-log scale. See Appendix, section A3, for more detailed explanation of modelling age using splines.

Figure e-4: Estimated associations between risk factors and PHN, with minimum number of days follow-up required lowered to reduce excluded patients



ORs are adjusted for age (modelled as a 5-knot restricted cubic spline to allow for non-linearity unless otherwise specified[1]), gender, socioeconomic status, HIV, leukaemia, lymphoma, myeloma, hematopoietic stem cell transplantation, other unspecified cellular immune deficiencies, immunosuppressive therapies, rheumatoid arthritis, systemic lupus erythematosis, inflammatory bowel disease, COPD, asthma, chronic kidney disease, depression, personality disorder, diabetes, recent cancer diagnosis, smoking, BMI category, site of zoster and antiviral use. Note: The main analysis includes only patients followed up for at least 365 days following rash onset (Risk of PHN 5.8% (6956/119413). [1]Age not modelled as a 5-knot restricted cubic spline but included as a linear effect, with slopes changing at age 50 and 81. The two sensitivity analyses lowered the restrictions on follow-up time, so all patients followed up for 180 and 120 days were included in the analysis (Risk of PHN 4.9% (6345/129592) and 3.1% (4145/133312) respectively). Please note the y axis are not identical for all graphs. OID=other immune deficiencies. COPD=Chronic obstructive pulmonary disorder. HSCT=hematopoietic stem cell transplantation.

†Adjusted for age (modelled as a 5-knot restricted cubic spline to allow for non-linearity unless otherwise specified), gender, socioeconomic status, HIV, leukaemia, lymphoma, myeloma, other unspecified cellular immune deficiencies, immunosuppressive therapies, rheumatoid arthritis, systemic lupus erythematosis, inflammatory bowel disease, COPD, asthma, chronic kidney disease, depression, personality disorder, diabetes, recent cancer diagnosis, smoking, BMI category, site of zoster and antiviral use. Interaction terms between age and other risk factors were added one at a time into the multivariable regression model. [1]Measured by Index of Multiple deprivation score. [2]Includes patients currently taking a 14 day course of immunosuppressive medications, or terminating a 14 day course of immunosuppressive medications less than one month prior to the zoster diagnosis. Oral corticosteroid prescriptions were required to be high dose (≥20mg per day).

Table e-3: Sensitivity analysis using alternative definitions of PHN

*PHN at 30 days: same definition as PHN at 90 days, but gathering evidence from 30-365 days following zoster. †Adjusted for age (modelled as a 5-knot restricted cubic spline to allow for non-linearity unless otherwise specified), gender, socioeconomic status, HIV, leukaemia, lymphoma, myeloma, hematopoietic stem cell transplantation, other unspecified cellular immune deficiencies, immunosuppressive therapies, rheumatoid arthritis, systemic lupus erythematosis, inflammatory bowel disease, COPD, asthma, chronic kidney disease, depression, personality disorder, diabetes, recent cancer diagnosis, smoking, BMI category, site of zoster and antiviral use.[1]ORs estimate the effect of a 10-year increase in age on PHN derived, in age groups <50, 50-79 and ≥80, from piecewise linear splines. [2]Measured by Index of Multiple deprivation score. [3]Includes patients currently taking a 14 day course of immunosuppressive medications, or terminating a 14 day course of immunosuppressive medications less than one month prior to the zoster diagnosis. Oral corticosteroid prescriptions were required to be high dose (≥20mg per day).

Table e-4: Relative risk of diagnosed, probable or possible PHN by gender (N=119,413)

Ophthalmic zoster	7.9	1.95 (1.73-2.19)
CONTROL RISK FACTOR: Hypothyroidism	10.9	1.01 (0.90-1.14)

†Adjusted for age (modelled as a 5-knot restricted cubic spline to allow for non-linearity), gender, socioeconomic status, HIV, leukaemia, lymphoma, myeloma, hematopoietic stem cell transplantation, other unspecified cellular immune deficiencies, immunosuppressive therapies, rheumatoid arthritis, systemic lupus erythematosis, inflammatory bowel disease, COPD, asthma, chronic kidney disease, depression, personality disorder, diabetes, recent cancer diagnosis, smoking, BMI category, site of zoster and antiviral use. [1]Calculated by dividing the total number of face-to-face or telephone consultations, by the total years of follow-up prior to zoster diagnosis for each patient and calculating the mean number of consultations per year for patients with each risk factor. [2]Measured by Index of Multiple deprivation score. [3]Includes patients currently taking a 14 day course of immunosuppressive medications, or terminating a 14 day course of immunosuppressive medications less than one month prior to the zoster diagnosis. Oral corticosteroid prescriptions were required to be high dose (≥20mg per day).

†Adjusted for age, gender, socioeconomic status, HIV, leukaemia, lymphoma, myeloma, other unspecified cellular immune deficiencies, immunosuppressive therapies, rheumatoid arthritis, systemic lupus erythematosis, inflammatory bowel disease, COPD, asthma, chronic kidney disease, depression, personality disorder, diabetes, recent cancer diagnosis, smoking and BMI category. Please note hematopoietic stem cell transplantation and other unspecified cellular immune deficiencies were excluded due to too few numbers. Interaction terms between antiviral use and other risk factors were added to the model one at a time. ††P-value for interaction. [1]ORs estimate the effect of a 10-year increase in age on PHN derived, in age groups <50, 50-79 and ≥80, from piecewise linear splines. [2]Measured by Index of Multiple deprivation score. [3]Includes patients currently taking a 14 day course of immunosuppressive medications, or terminating a 14 day course of immunosuppressive medications less than one month prior to the zoster diagnosis. Oral corticosteroid prescriptions were required to be high dose (≥20mg per day). *Patients excluded were those diagnosed with zoster in HES, or with a hospital visit for zoster (primary diagnosis of any episode) in the 7 days after first zoster diagnosis, patients without linked HES data and patients with evidence of non-truncal zoster, as their antiviral use may not be recorded in CPRD.

7.4. Chapter summary

Identifying risk factors for PHN in CPRD

- A large cohort study followed up 119,413 zoster patients, of whom 5.8% developed PHN. A range of medical conditions and patient characteristics were associated with increased risk of PHN, including; autoimmune conditions (RA, SLE and IBD), COPD, depression, diabetes, asthma, lower SES, smoking, under- or overweight and non-truncal zoster.
- Antiviral use was not associated with PHN. There was some evidence that the increased risk of PHN with SLE, leukaemia, COPD and smoking was attenuated in patients given antivirals.
- The strongest risk factors for PHN are severely immunosuppressive conditions, which are vaccine contraindications for the currently available zoster vaccine, emphasising the need for alternative risk reduction strategies (such as a non-live vaccine and antiviral prophylaxis) among these groups.

Chapter 8: Summary and conclusions

The research presented in this thesis aimed to improve the understanding of risk factors for zoster and PHN to inform vaccination policy, by undertaking a literature review, a systematic review and meta-analysis, and three large observational studies using UK EHR data. The first observational study, a case-control study (reported in chapter 4) examined risk factors for zoster. The second observational study, a cohort study (reported in chapter 7) examined risk factors for PHN. An additional observational study was conducted to evaluate the extent to which antiviral treatment during acute zoster is administered according to treatment guidelines.

Specific issues relating to individual studies were discussed within the preceding chapters. This final chapter provides an overview of the key findings from these individual studies, in the context of previous research, and then sets out the strengths and limitations of using EHR data to address the research questions in this thesis. The chapter ends by highlighting implications for clinical practice and outlining unanswered questions for future research.

8.1. Overview of key findings

8.1.1. Risk factors for zoster

8.1.1.1. What was already known on this topic

- A zoster vaccine became available in 2006 and vaccination programmes are underway in a number of high-income countries including the UK, USA, Canada and Japan. The zoster vaccine is currently targeted at older individuals only, as increasing age is one of the few well-established risk factors for zoster.
- The other well known risk factor for zoster is severe immunosuppression, explaining around 5% of zoster cases. However, patients with severe immunosuppression are not eligible for the currently available vaccine, due to safety concerns with a live vaccine.
- As described in the literature review of zoster risk factors (see chapter 2) a number of clinical conditions not currently listed as contraindications for the zoster vaccine were associated in some studies with an increased risk of zoster; these included certain autoimmune conditions such as RA, SLE, and IBD, and other chronic conditions such as diabetes mellitus, COPD, CKD, asthma and depression.

- However, these studies tended to be small and inadequately powered to investigate the association of these conditions with zoster.
- Studies also suffered from poor control of confounding factors (for example age was often included as a categorical variable with wide intervals) and studies rarely investigated whether the effects of some conditions were mediated by immunosuppressive drugs.
- Additionally, few studies assessed several risk factors simultaneously, and the lack of a consistent methodological approach did not allow direct comparison of the relative strength of various risk factors.
- Finally, it is not clear if younger age groups, particularly individuals with specific patient characteristics, might benefit from vaccination. The zoster vaccine is currently only licensed for use in patients aged ≥50 years, however over 30% of zoster cases occur under the age of 50 years. No previous studies have assessed how the effects of a broad range of comorbid conditions on zoster risk vary by age.

8.1.1.2. What the study adds

- The zoster case-control study (described in chapter 4) showed that the highest risk of zoster was associated with severe immunosuppressive conditions, for example lymphoma (adjOR: 3.90, 99% CI 3.21-4.74) and myeloma (adjOR: 2.16, 99%CI 1.84-2.53). This study finding highlights how the patients most in need of zoster prevention are not able to benefit from the currently available zoster vaccine, emphasising the need for alternative risk reduction strategies in this group, such as non-live vaccines and antiviral prophylaxis.
- Consistent with previous studies, patients with autoimmune conditions (specifically, SLE, IBD and RA) were 1.3 to 1.7 times more likely to develop zoster, compared to the general population.
- Patients with the respiratory conditions asthma or COPD were at 20 to 30% greater risk of zoster.
- The effects of RA, IBD, COPD and asthma were attenuated after adjusting for immunosuppressive medications. Each of these conditions are frequently treated with immunomodulating drugs and this finding suggests that at least part of the risk associated with these conditions is mediated by the drugs, rather than the disease itself.

- The other conditions which were associated with increased risk of zoster, albeit with associations that were smaller than reported in previous studies (ranging from 1.1 to 1.3 times the odds), were depression, CKD and type 1, but not type 2, diabetes.
- The relative effects of the observed risk factors were larger in younger patients. For example, the OR point estimates for CKD were 1.53, 1.21 and 1.11 among patients 18-49 years, 50-59 years and 60-69 years respectively. The estimated rate of zoster in younger patients with CKD still remained low, due to the underlying low rate in younger patients. However, this finding raises questions about the utility of vaccinating younger patients with certain characteristics.
- Of 97,789 zoster cases aged under 70 years, 3619 (3.7%) had a predicted risk of zoster as high as that for the general population aged 70 years or over. This finding indicates there may be some benefit to targeting specific patient groups under 70 years of age, though cost-effectiveness studies would be required to further investigate whether this approach is warranted.
- By including a variety of risk factors in one study, it was possible to compare the strength of association between different risk factors. This approach also allowed tight control of known and potential confounders.

8.1.2. Which zoster patients receive antivirals?

8.1.2.1. What was already known

- Antivirals are recommended for all immunosuppressed patients presenting with zoster and certain immunocompetent patients (specifically, people aged ≥50 years, or individuals with ophthalmic zoster, other non-truncal disease, moderate to severe pain or rash). Treatment within 72 hours of rash onset is recommended, although antivirals may be given up to one week after zoster onset. The evidence base suggests that antiviral treatment reduces the severity and duration of the acute zoster episode, though the effect of antiviral treatment on PHN is disputed.
- Little research existed exploring the extent to which antiviral prescription guidelines are adhered to. A previous study of CPRD data indicated that antivirals were under-prescribed in the UK; 56.3% of 27,225 immunocompetent patients with zoster aged ≥50 years received antivirals between 2000 and 2006. However, there were no data on the proportion of immunosuppressed patients receiving antivirals in UK primary care.
- Studies from the USA, Italy, and Australia reported higher proportions of adult patients with zoster receiving antiviral prescriptions, of between 70 to 80%, though they included secondary care data and the health care systems have significant differences.

- Previous studies have tended to report overall use of antivirals, rather than use by specific risk groups, therefore it is difficult to identify who is receiving antivirals and whether certain patient groups are under-prescribed antivirals.

8.1.2.2. What the study adds

- The descriptive antiviral study (described in chapter 5) demonstrated that of 142,216 zoster patients diagnosed with zoster between 2000 and 2011, 58.1% received antivirals within 7 days of zoster diagnosis, in keeping with an earlier study in CPRD.
- This study additionally looked at patterns of use, in both immunosuppressed and immunocompetent patients, to better understand who receives antivirals in UK primary care.
- The study demonstrated that antivirals are under-prescribed in patients for whom guidelines recommend treatment. Specifically:
    - Although immunosuppressed patients were 30% more likely to receive antivirals than immunocompetent patients, antivirals were not given routinely to this group. In total, 35.1% of patients with severe immunosuppression did not receive antivirals in primary care.
    - The proportion of patients receiving antivirals increased with age up to 65-74 years, then declined among patients aged ≥85 years, for whom only 56.8% received treatment.
    - Patients were less commonly prescribed antivirals in primary care if they had ophthalmic (proportion given antivirals, 49.4%) or other non-truncal zoster (30.9%) than patients with zoster in whom site of zoster was not specified (58.4%). This was a surprising finding, as the guidelines clearly advise treatment for these patients. This finding may in part be explained by patients with zoster in "high risk" sites being referred immediately to secondary care for treatment or attending emergency departments.
- Being female and of higher SES were associated with higher antiviral receipt, which may be explained by greater health-seeking behaviours in these groups Antiviral prescriptions increased every year from 45.7% in 2000 to 65.3% in 2010 and the trend remained after adjusting for confounders. Use also varied by region, with highest use in Northern Ireland (67.7%) and lowest use in the north-east of England, specifically the Yorkshire and Humber region (51.9%), an effect which remained after adjusting for covariates.

- Patients with autoimmune conditions considered to be associated with moderate immunosuppression were more likely to receive antivirals; in particular, there was greater antiviral use among patients with RA and SLE, irrespective of whether they were receiving immunosuppressive therapy, and also patients with IBD treated with immunosuppressive therapy.
- Under-treatment with antivirals cannot be attributed to adverse effects or cost, as these drugs are well-tolerated and relatively inexpensive. Patients may present too late to receive antiviral therapy, however previous research from UK data suggests that the majority of patients present soon after rash onset. It is therefore plausible that under-treatment may reflect poor adherence to treatment guidelines.

8.1.3. Risk factors for PHN

8.1.3.1. What was known

- Older age was a well-known risk factor for PHN, with very few cases occurring under the age of 50 years.
- Other frequently reported risk factors for PHN related largely to characteristics of the acute zoster episode, such as the severity of the acute pain. Despite these characteristics being commonly cited as predictors of PHN, the evidence had never been systematically reviewed and the magnitude of their effect was largely unknown.
- Finally, an understanding of patient characteristics and conditions identifiable before the zoster episode which may increase the risk of PHN and potentially be useful when considering vaccination policy, had yet to be summarised.

8.1.3.2. What the systematic review adds

- The systematic review and meta-analyses of risk factors for PHN within zoster cohorts (described in chapter 6) demonstrated that risk factors for PHN are poorly understood and that existing evidence is often conflicting and underpowered.
- Meta-analyses demonstrated that features of the acute zoster episode, including prodromal pain, severe acute pain or rash and ophthalmic involvement, were associated with greater than twice the risk of PHN.
- Regarding vaccine-targetable risk factors for PHN, the review demonstrated a clear increased risk of PHN with greater age; nine studies reported an effect estimate for a

ten-year increase in age on PHN risk, with estimates ranging from 1.22 to 3.11. Exactly how the risk of PHN varies as people age is not understood.

- There was a suggestion from three out of five studies in the systematic review that patients with immunosuppression may be at greater risk of PHN. However, the evidence was conflicting and different definitions of severe immunosuppression were used, limiting the ability to compare study results.
- Other patient conditions associated with an increased risk of PHN (investigated in single studies only) were SLE, recent trauma and personality disorder symptoms. There was no evidence of higher PHN risk with depression (in four studies) or cancer (in five studies). Diabetes was associated with increased risk of PHN in one of four studies.
- No previous studies were identified which investigated the effects of RA, IBD, COPD, asthma or CKD on PHN risk.
- There were key differences between studies included in the review, such as: (i) the demographic characteristics of participants, particularly their age distribution; (ii) the definition of PHN used, for example assessing pain at one, three or six months following zoster, as well as including "any" or "severe pain" following zoster; and (iii) differences in the confounders accounted for in the analyses. Comparisons between study results must therefore be made cautiously.
- Overall the majority of studies currently published are limited in size, reducing their power to detect associations; in total, 17 out of 19 studies included in the review had under 1000 participants. Although the review required effect estimates to be age-adjusted, many studies included age as a binary or categorical variable with wide intervals, potentially leading to residual confounding by age.

8.1.3.3. What the original research study adds

- The cohort study (described in chapter 7) showed that PHN risk is increased for a number of patient characteristics and comorbidities, most notably age and immunosuppressive conditions. The study both confirmed previously described risk factors for PHN, as well as identifying novel risk factors.
- One of the most well-reported and strongest risk factors for PHN is age. This study confirmed older age as a key risk factor. The risk rose most sharply between 50 and 79 years, where a 10-year increase in age within this age-band was associated with 70% increased risk of PHN. A 10-year increase among patients aged 80 years and above was

associated with just 10% increased risk of PHN, although patients in this age group would have a higher baseline risk.

- Previous research on the impact of severe immunosuppression on PHN was inconclusive. This study demonstrated that severe immunosuppression was a strong risk factor for PHN. Furthermore, rather than combining patients with any condition or course of therapy associated with severe immunosuppression, this study had sufficient power to assess the effect of specific conditions and therapies on PHN risk. Leukaemia or lymphoma diagnosed in the previous two years, myeloma, other unspecified cellular immune deficiencies, or recently taking a course of high-dose (≥20 mg per day) corticosteroids, were each associated with a more than doubling in the risk of PHN.
- Conditions also associated with increased risk of PHN, and recognised in previous studies, comprised SLE, which was associated with over 80% increased risk of PHN, and type 2 diabetes, which was associated with 20% increased risk. In contrast with previous research, this study suggested recent depression was associated with almost 40% increased risk of PHN, whereas there was no evidence that personality disorder predicted PHN, after adjusting for covariates. Novel risk factors for PHN, not identified in any previous research, included RA, IBD, COPD and asthma.
- This study was one of the few to look at the association between lifestyle risk factors and PHN. Being a current or ex-smoker, as well as being underweight or obese, was associated with 10 to 30% greater risk of PHN.
- The only clinical feature of acute zoster available in CPRD was site of zoster and, consistent with previous studies, PHN was twice as common in patients with non-truncal (including ophthalmic) zoster.
- The study was also unique in exploring the effects of antiviral use. Antiviral use was not associated with PHN (OR=1.04, 0.97-1.12). There was also some weak evidence that the increased risk of PHN associated with leukaemia, SLE, COPD and smoking was less pronounced in patients given antivirals.
- This study benefited from being the largest to date exploring risk factors for PHN, as well as tightly accounting for the confounding effects of age by using a continuous non-linear function in the modelling.

8.2. Strengths and weaknesses of using electronic health records for research into zoster and PHN

The studies included in this thesis used primary care data from the UK (CPRD), linked to hospitalisation (HES) data. As data are routinely collected in these databases, they are hugely advantageous for researchers, as they reduce the time and cost involved in traditional data collection. This section reviews the strengths and weaknesses of using these databases in addressing the study questions. As HES data were used specifically to identify zoster and PHN patients, and as the large majority of individuals with zoster and PHN were identified in CPRD, this section largely refers to CPRD data.

8.2.1. Strengths

8.2.1.1. Size and long-term follow-up

A key strength of CPRD is its size, which allowed the studies to look at less common conditions, such as SLE, and explore age interactions, with sufficient statistical power. For example, the case-control study in chapter 4 included over half a million individuals (and more than 140,000 zoster cases) who had an average of more than 8 years active follow-up. Furthermore, the cohort study in chapter 7 was the largest known analysis to date of PHN risk factors. In all three studies, there was sufficient power to look at certain individual conditions associated with immunosuppression, rather than combining these conditions into one category.

8.2.1.2. Breadth of data

CPRD is one of the few EHR databases in the world holding information on lifestyle data, including BMI, smoking status, alcohol use and SES, as well as clinical diagnoses and prescription data. The availability of lifestyle and anthropometric data allowed these factors to be explored and accounted for in the analyses, in contrast to much previous research on zoster and PHN risk factors. Furthermore, CPRD is one of the few large and ongoing databases to have linkage to secondary care data, which was used to identify cases of zoster and PHN diagnosed in hospital.

8.2.1.3. Prospectively collected data

Another strength of using CPRD and HES is that data are collected prospectively, as patients attend their general practice or hospital for healthcare. This meant that the studies assessing risk factors for zoster and PHN were not subject to biased ascertainment of past exposure status (when a patient's outcome influences their memory and thereby reporting of the exposure) or observer bias (where the patient's outcome influences the observer's recording of the exposure). Furthermore, use of this prospectively collected data meant the matched

case control study of zoster risk factors was nested in the CPRD cohort. This meant controls were drawn from the same population that gave rise to the cases, thus reducing the possibility of selection bias.

8.2.1.4. Representativeness

As described in chapter 3, CPRD patients are broadly representative of the UK population in terms of age, sex and ethnicity (although the database may not fully represent all practices in the UK in terms of geography and size).[85] This means that by selecting all patients with zoster, and suitable controls, the conclusions for the studies presented in this thesis are likely to have good external validity and be generalizable to the UK population.

8.2.2. Limitations

Although CPRD and HES have many strengths for investigating the study questions explored in this thesis, it must also be acknowledged that using the databases introduced some limitations. The limitations of each study have been described within the individual chapters. Below is a summary of these discussions, considering the research project as a whole.

8.2.2.1. Information bias

Information bias may have been introduced due to measurement or ascertainment errors within CPRD and HES data. In the following section misclassification of zoster, PHN and other covariates are discussed, along with the potential impact of this misclassification on the study findings.

Misclassification of zoster

Zoster diagnosis in UK primary and secondary care is based on clinical judgement, without laboratory confirmation. As discussed in chapter 4, zoster diagnoses have not been validated in CPRD or HES. However a validation study of zoster in a primary care setting in the Netherlands demonstrated a high PPV of zoster diagnosis of 91%, when confirmed by the presence VZV of antibodies.[198]

The most likely misclassification of zoster is believed to be with herpes simplex. However, herpes simplex rarely presents with a dermatomal distribution, therefore the extent of this misclassification in this body of research is believed to be minimal. If patients with herpes simplex were incorrectly included as zoster cases in the matched case-control study (chapter

4), assuming simplex is not associated with the risk factors of interest, any misclassification would have led to an underestimation of the effect estimates. If the risk factors of interest were associated with greater risk of herpes simplex, there might have been an overestimation of effect estimates. In chapter 7, the analysis of PHN risk factors within a zoster cohort, patients with herpes simplex potentially misdiagnosed as zoster patients were removed in a sensitivity analysis (specifically, zoster cases with zoster codes appearing within the year following first zoster diagnosis, many of whom had a further antiviral prescription on the same day) and there was no appreciable impact on the study findings.

Zoster diagnoses may be missed in the EHR data, either due to: 1) misdiagnosis of zoster, for example misdiagnosing zoster cases as herpes simplex or difficulties in diagnosing zoster in the rare situation in which a rash does not appear, known as zoster sine herpete; or 2) zoster being recorded in the free text but not coded in CPRD; or 3) zoster patients not attending health services, for example if the pain is mild or patients are unable to seek healthcare. Use of both CPRD and linked HES data allowed more complete capture of zoster cases attending either healthcare setting. However, the frequency with which diagnoses of zoster are *not* captured in either CPRD or HES is not known. Missed zoster diagnoses may be more common in younger patients among whom zoster is less prevalent and may be less severe. Studies establishing the validity of "non-diagnoses" in EHR data (i.e. patients *without* specific diseases) are rarely carried out, as this requires sampling a number of patients *without* the disease (whereas the PPV only requires sampling of patients *with* the disease).[89] Assuming inclusion of some zoster patients in the control pool is random and non-differential according to the exposures, this misclassification would have caused an underestimation of effect estimates.

Patients were required to have 12-months registration in CPRD without a zoster diagnosis, to exclude past history of zoster recorded shortly after registration. It is possible that a 12-month cut-off was insufficient to remove past history of zoster or PHN cases (misdiagnosed as acute zoster). A 24-month cut-off may have increased the likelihood of the included patients being incident. Previous research has however shown that the incidence rate of zoster is slightly higher in CPRD during the first 3 months after registration, however reached baseline levels 4-6 months following registration, suggesting the chosen cut-off was appropriate.

Validity of zoster diagnosis timing

The precise timing of zoster onset may not always be attainable from CPRD and HES data. The date at which zoster patients presented to their GP with zoster was used as a proxy for rash onset date. In reality, the true date of rash onset will, in some cases, be a few days prior to

this. As acknowledged in chapter 7, incorrect rash onset date might have affected the observed null association between antiviral use during acute zoster and PHN; some studies have reported that antivirals are effective at reducing PHN risk if given *within 72 hours* of rash onset, therefore delay in presenting to primary care may explain the null finding.

Misclassification of postherpetic neuralgia

As with zoster, PHN has not been validated in CPRD or HES. As discussed in detail within chapter 3, section 3.3.2, diagnosing PHN in EHR databases is a particular challenge. The difficulties result from a variety of reasons, including different definitions of PHN being used, PHN treatments being non-specific to PHN and therapeutic indication not being recorded in CPRD.

As discussed in chapter 3, of particular concern was that patients with depression were wrongly defined as having PHN, due to the use of tricyclic antidepressants in defining PHN patients. Several steps were taken to reduce this misclassification, such as ensuring all PHN cases had recently been diagnosed with zoster, ensuring PHN cases did not have diagnosis codes suggesting depression when PHN was defined through use of tricyclic antidepressants, and ensuring prescriptions were "new" (no previous prescriptions of a tricyclic antidepressant in the 12 months to two weeks prior to zoster). However, the association between PHN and depression disappeared when PHN was defined through use of diagnosis codes only (i.e. a Read or HES code for PHN), therefore it is possible that some misclassification of PHN occurred, which may have increased the association between depression and PHN.

Part of the PHN definition incorporated use of anti-convulsants and hence patients with a history of epilepsy were excluded from the study cohort. However, anticonvulsants can also be used a mood stabiliser for patients with bipolar, personality disorder and schizoaffective disorder. Therefore, there may have been some misclassification of PHN cases resulting from the inclusion of anticonvulsants as part of the PHN definition, which could have further increased the association observed between depression and PHN.

It is also possible that some individuals with PHN will have been included in the non-PHN comparison cohort; this misclassification is potentially supported by the relatively low prevalence of PHN, compared to other non-EHR studies. As discussed in chapter 7, it was hypothesised *a priori* that misclassification of PHN status may be differential according to the investigated PHN risk factors, because patients with risk factors of interest may attend their

general practice more frequently, and thus be more commonly diagnosed with PHN. However, little evidence was found to suggest the presence of this bias (ascertainment bias, see section 7.2.4). Instead, misclassification of PHN status is more likely to be non-differential according to the explored PHN risk factors and therefore PHN patients may have made a small contribution to the risk estimates of the comparison group, which would marginally reduce the reported risk estimates.

Finally, differential health-seeking behaviours may be driving the increased risk of PHN among females (compared to males), as women are known to attend general practice more commonly than men.

Misclassification of other conditions

Using stand-alone CPRD to define medical conditions

Although GPs are requested to record all patient diagnoses, recording of some clinical outcomes in CPRD may be incomplete, particularly those made in secondary care. Hospital letters will be sent to the GP and may be stored on the system, but a Read code may not always be entered, therefore the information may be missed by researchers. Most risk factors in this study requiring secondary care were chronic and of sufficient significance that they are likely to be recorded in the patient's primary care records; many conditions, such as diabetes, are treated largely in primary care (and also from 2004 diabetes has been part of QoF) and for these conditions this may be a reasonable assumption. However, since the research in this thesis was conducted, there has been evidence to suggest that using stand-alone databases to identify patients with certain conditions can lead to under-capture. This misclassification appears particularly pertinent to acute events such as myocardial infarction[199] and community acquired pneumonia,[200] but also with regard to some chronic conditions such as asthma.[201] Therefore, it seems likely that some patients with the conditions of interest will have been misclassified as "unexposed" patients. Misclassification of medical conditions is likely to be non-differential according to the outcomes (zoster or PHN), therefore in the risk factor analyses this would have caused an underestimation of effect estimates.

Incomplete clinical information

Detailed clinical information, which may be gathered in a traditional epidemiological study with active data collection, is also not always available to CPRD researchers. In CPRD, some information may never be recorded, or may be within the free text field. Incomplete clinical detail may have led to misclassification. For example, regarding the categorisation of diabetes

into type 1 or 2, the definition relied on: 1) age at diagnosis, which may be problematic if patients moved practice after their first diagnosis of diabetes; and 2) treatment, which could be missed if only given in secondary care. This categorisation may have led to some type 1 diabetes patients being misclassified as type 2 diabetes, if their real age of first diagnosis was earlier than recorded and they were receiving insulin in secondary care.

Misclassification of prescriptions

Although the CPRD has excellent capture of primary care prescriptions, there are some limitations. First, CPRD doesn't provide data on adherence to treatment or timing of treatment initiation; the issue date may not necessarily be the date the prescription was collected, or the date the patient started using the drug. The issue of non-adherence is particularly relevant to ICS prescriptions, which are often used intermittently when required. Regarding severely immunosuppressive drug exposures prior to zoster onset (for example oral corticosteroids or methotrexate), non-adherent patients, or those initiating treatment after the issue date, could be misclassified as having been exposed when in fact they were unexposed. This misclassification may be differential according to the outcomes, zoster and PHN, specifically that non-adherent patients may be less likely to develop zoster or PHN. Thus any misclassification due to non-adherence may have caused an underestimation of the effects of immunosuppressive drugs on zoster risk.

Secondly, neither CPRD nor HES record therapy given in secondary care. Antivirals given in secondary care would be missed, and as acknowledged in chapter 5, may partly explain the low use of antivirals among patients with ophthalmic or non-truncal zoster, for whom guidelines specifically recommend treatment. Additionally, immunosuppressive medications may be given in hospital, for example chemotherapy and biologics, and thus may be unrecorded in primary care. Part of the effect of cancers studied here (specifically, leukaemia, lymphoma and myeloma) will have been driven by chemotherapy and it was not possible to disentangle the effect of the cancers themselves versus their treatments. Regarding anti-TNF biologic medications, these drugs do not form the mainstay of treatment in the UK for inflammatory conditions, but are used in approximately 10% of RA patients and 13% of adult Crohn's disease patients.[202] As described in chapter 2, these drugs may be associated with an increased risk of zoster in RA and IBD patients. Part of the associations observed between autoimmune conditions and zoster or PHN may therefore be explained by biologic or other immunosuppressive therapy not captured in the GP records.

As discussed in section 3.4.2, daily prescription doses for oral corticosteroids were cleaned and some missing data imputed. This imputation may have led to some misclassification of high-dose oral corticosteroid exposure; however, this misclassification is unlikely to be related the outcomes (zoster and PHN), therefore estimates of the effect of oral corticosteroids on zoster risk would only have been reduced toward the null.

Finally, over the counter medications are not recorded in CPRD. This is not an issue for identifying antiviral or immunosuppressive medications, as these drugs are prescription only. However, patients may self-medicate for PHN with over the counter pain medications, if the pain can be controlled with mild analgesics, therefore some PHN patients are likely to have been misclassified. As explained in chapter 7, this limitation may not cause biased results, however it may limit the generalisability of the results to patients with severe, rather than mild, PHN.

8.2.2.2. Confounding by indication

Confounding by indication can occur because within observational data, drugs are not randomly allocated but may instead be indicated for a disease based on severity and prognosis. Therefore risk of the outcome, prior to treatment, may not be similar between treated and untreated individuals. For example, in chapter 7, *a priori* it was anticipated that any protective effect of antiviral use during acute zoster on PHN risk may be attenuated; this is because patients with more severe zoster are more likely to receive antivirals as well as being at greater risk of PHN, potentially masking any protective effect of antivirals. In the final multivariable model, there was no association between antivirals and PHN, and this observation may therefore be explained by confounding by indication. Two statistical methods exist which can, in theory, better deal with confounding by indication: 1) propensity scores.[203] and 2) instrumental variables. [204] These methods will be considered in future analyses.

8.2.2.3. Residual confounding

CPRD data are collected primarily as a tool for physicians to record a patient's medical history and therefore certain data may not be sufficiently recorded to fully adjust for the confounding effects of that variable. Residual confounding by measured variables may arise from two sources. The first source is from confounders being misclassified. For example, as described in

section 8.2.2.1 above, part of the observed effect between RA and zoster may be due to residual confounding by biologics. The second source is from confounders being defined in broad categories, and residual confounding arises if the risk of the outcome varies within a category of the confounder. For example, patients classified as current smokers would have represented a range of smoking habits, from occasional to very heavy smokers, and this may have caused residual confounding by smoking.

In addition to incomplete capture of included risk factors, uncontrolled variables not available within CPRD may have caused residual confounding. For examples, physicians do not routinely record certain factors associated with zoster, such as exposure to individuals with varicella and dietary habits, such as fruit intake. The possibility of residual confounding incurred from not accounting for two unmeasured factors, psychological stress and ethnicity, are discussed below.

Psychological stress

Despite the evidence-base being limited and inconsistent, there is some suggestion that psychological stress may be an important risk factor for zoster (as outlined in chapter 2). The research presented in this thesis did not account for psychological stress. Capturing all psychological stress in CPRD would have been challenging, as stress may be induced by a wide range of conditions or events, such as depression, anxiety, self-harm, bereavement, job loss or divorce. Furthermore, many people who experience acute or chronic stress will not seek care from their GP. It is therefore plausible that this study may suffer from residual confounding by psychological stress. If stress is a risk factor for zoster and was equally distributed among exposed and unexposed patients for specific conditions, this would have led to an underestimation of effect sizes. However, it is plausible that stress may mediate the relationship between some of the conditions investigated in this thesis and zoster (in other words, stress may be on the causal pathway between the exposures and zoster). If this scenario is correct, it would have been inappropriate to control for stress.

Ethnicity

At the time this research project was planned, little was known about the reliability of ethnicity data and a decision was made not to investigate ethnicity as a covariate. Research has subsequently shown that for patients registered with a general practice after April 2006, ethnicity data in CPRD alone is available for 78.3% of patients.[205] However, the authors recommend not using ethnicity data recorded in patients registered prior to April 2006, as

recording is low and likely to be selective. Further investigation has shown that less than 5% of the zoster cases and their matched controls from the study in chapter 4 were registered after April 2006; thus, in retrospect, the decision not to include ethnicity data remains valid. However, not including ethnicity as a covariate may have implications on the study findings. As mentioned in chapter 4, the lack of association between type 2 diabetes and zoster may be partly driven by negative confounding by ethnic group (patients of South Asian origin are at higher risk of type 2 diabetes, yet lower risk of zoster).

8.2.2.4. Selection bias due to missing data

In the thesis, lifestyle data, including BMI, smoking and alcohol were explored and accounted for in the analyses. All these variables contain some missing data. These lifestyle data are recorded opportunistically for many patients and missing data are unlikely to be 'missing completely at random'. For example, BMI completeness is higher in females, in clinical subgroups where BMI recording is incentivised (such as type 2 diabetes) and in older age groups.[125] It is also plausible that the missing data depend on the variable itself (for example, patients with healthy BMI may not have their BMI recorded by the GP). In the main analyses in chapter 4 and 7, patients with missing data were excluded from the analysis (complete case analysis). This method may lead to biased effect estimates, as the included sample are unlikely to be representative of the full cohort, potentially introducing selection bias. However, complete case analysis is valid, if the reasons for missing-ness are unrelated to the outcome, given the covariates.[206] In terms of the lifestyle variables BMI, smoking and alcohol use, it is assumed that non-recording of these variables is unlikely to be related to developing zoster or PHN.

However, as an alternative approach to handling missing data, data that was missing for BMI, smoking and alcohol was also accounted for through multiple imputation in a sensitivity analysis. That the study findings were consistent when applying a complete case and multiple imputation method suggests the results are robust, and major selection bias is unlikely to have been introduced.

8.2.2.5. Data on underlying mechanisms

The mechanisms through which exposures increase the risk of zoster and PHN is assumed to be through impairing T cell-mediated immunity. It was not possible to confirm the pathway in this thesis, as the CPRD doesn't contain biological markers of cellular immune-suppression.

8.2.2.6. Multiple testing

The risk factor analyses in chapter 4 and 7 involved testing multiple associations. Testing multiple associations results in the possibility that some of the observed "statistically significant" associations may have occurred by chance. However, in order to protect against this, 99% CIs were used. Furthermore all risk factors were specified *a priori*, based on previous epidemiological research and/or supporting data regarding plausible biological mechanisms.

8.2.2.7. Lack of clinical information on risk factor sub-groups

The EHR data was insufficiently detailed to investigate potentially important differences between sub-groups of certain risk factors. For example, all stages of CKD severity were grouped together, as were symptomatic and asymptomatic HIV, the latter of whom may not be associated with cell-mediated immune suppression.[104] It is therefore not possible to see how the effects of these risk factors on zoster and PHN varied according to severity of disease. Furthermore, it was not possible to determine whether the observed effects were driven solely by patients with more severe disease.

8.3. Implications for clinical practice

Recognising that certain patients are at increased risk of zoster and PHN, as well as identifying the under-prescription of antivirals in patients with zoster, could have important implications for clinical practice:

- This thesis adds to the case for vaccinating individuals against zoster prior to the introduction of immunosuppressive therapies. Given the increased risks of zoster and PHN in patients on immunosuppressive treatment, and the contraindication to use the currently available live vaccine in severely immunosuppressed individuals, vaccination prior to commencement of immunosuppressive treatment may warrant consideration, although evidence to support this strategy is currently lacking. The new sub-unit vaccine which has been designed for use in patients with immunosuppression (and is currently being investigated in Phase 3 trials) may enable vaccination in this group.

- This study highlights the need for greater prescribing of antivirals and considerations could be given to improving the implementation of the guidelines on antiviral prescription following acute zoster. Antivirals are important in lessening the time and severity of the acute zoster episode. Although antivirals have not conclusively been shown to protect against PHN, the study of PHN risk factors showed some weak evidence that their use may be associated with a reduction in PHN risk in patients with leukaemia, SLE, COPD and smoking. Together, these factors support better adherence to antiviral treatment guidelines during acute zoster.
- The UK guidelines for antiviral use currently recommend that patients presenting after 72 hours of zoster onset be given antivirals within one week of rash onset, if they are at high risk of severe shingles or complications. Considering that a number of conditions and patient characteristics have been identified which increase the risk of PHN in this thesis, consideration could be given to suggesting that patients with identified risk factors for PHN also be given antivirals if presenting after 72 hours of rash onset.

8.4. Implications for further research

8.4.1. Risk factors for zoster and PHN

- This study has identified a number of patient characteristics as risk factors for zoster and/or PHN. It also showed younger patients with certain conditions were at higher risk of zoster. Cost-effectiveness studies would be needed to determine whether vaccination of groups with particular characteristics would be worthwhile.
- Although this study has demonstrated that certain patient characteristics and conditions are associated with increased risks of zoster and PHN, further research is needed to understand the mechanisms underlying the increased risk, particularly for PHN for which the pathogenesis of continued pain is poorly understood.
- The safety of the currently available *Zostavax* vaccine in immunosuppressed groups is also poorly understood and its contraindication is largely based on expert opinion rather than clinical data. Further research assessing its safety among immunosuppressed patients is needed. Recent RCTs have supported zoster vaccine guidelines, such as a small RCT (n=295) demonstrating that the vaccine is safe in patients currently on a maintenance dose (5-20 mg per day) of corticosteroids[207] and preliminary results suggest HIV patients with CD4 counts ≥200 per mm^3 and on ART are not at increased risk of zoster after receiving the *Zostavax* vaccine.[208] However,

research among patients with current vaccine contraindications is needed. For example, there is some evidence from observational studies that autoimmune patients on anti-TNF biologics and non-TNF biologics may not experience an increased risk of zoster following *Zostavax* vaccination in the primary safety risk window (42 days following vaccination),[53] however trials are needed to confirm these findings to ensure the effects are causal.

- The new subunit vaccine offers more potential for use in immunosuppressed patients and requires further research on safety and efficacy in this group. As this newer vaccine is not live, it does not pose the same risk of triggering a varicella-like or herpes zoster illness as the *Zostavax* vaccine. Furthermore, initial results suggest the new subunit vaccine has limited safety concerns and appears equally as effective among older groups, wherein *Zostavax* vaccine efficacy is significantly reduced.[209]
- Work is needed to establish the role of psychological stress on zoster risk. Despite stress being viewed as an important risk factor among the lay public and medical professionals, stress has not been consistently shown as a risk factor in the epidemiological literature.
- Finally, this research used a current dose model when exploring the effect of prescription drugs on the risk of zoster and PHN; further research could take into account the impact of historical therapy on zoster and PHN risk.

8.4.2. Antiviral prescribing patterns in UK primary care

- Further research into the causes of under-prescription of antivirals to acute zoster patients, specifically among older and immunosuppressed groups, would be helpful in determining strategies to increase the number of patients given antivirals. For example a qualitative research study among GPs may help clarify reasons for non-prescription of antivirals, where the guidelines specify antivirals should be administered. This could then be followed up by a quantitative cross-sectional survey to determine the most common reasons for under-prescription of antivirals.
- Research on antiviral use during acute zoster is currently limited to assessing antiviral effectiveness when given within 72 hours of rash onset. This treatment window may be unrealistic in clinical practice, as there may be a delay of >72 hours between rash onset and presentation in primary care. Therefore, to further encourage physicians to prescribe antivirals, research into the effectiveness of antivirals given within a week of rash onset may be helpful.

8.5. Overall conclusions

Herpes zoster is a common disease with appreciable morbidity, which is preventable through vaccination. This thesis has carried out a systematic literature review, a literature review and two large observational studies using UK primary care data, to investigate risk factors for zoster and PHN. There was an increased risk of both zoster and PHN among patients with selected autoimmune conditions (RA, SLE and IBD), COPD, asthma and depression. The greatest risk of both zoster and PHN was among patients with severely immunosuppressive conditions, highlighting the need for alternative risk reduction strategies in this group, for which the new subunit vaccine appears promising. Whilst data on the underlying mechanisms were not part of the work described in this thesis, the increased risk of PHN among patients with autoimmune and other immunosuppressive conditions suggests that lower cell-mediated immunity may play an important role in the pathogenesis of PHN, as well as zoster. A third study also draws attention to the under-prescription of antivirals during acute zoster in UK primary care, suggesting physicians are not fully adhering to treatment guidelines. This thesis has highlighted a number of risk factors for PHN and zoster; cost-effectiveness studies are now needed to determine the value in providing zoster vaccination to patients with these risk factors.

Appendix I: Scientific protocol

The candidate was employed under an NIHR Clinician Scientist fellowship awarded to Sinéad Langan entitled, “The natural history and management of herpes zoster: the role of moderate immunosuppression from common diseases”. The scientific protocol can be found below.

The natural history and management of herpes zoster: the role of moderate immunosuppression from common diseases

Lay Summary

Shingles is a common disease with very important consequences that have lead to large scale vaccination programmes being introduced in the USA and planned in the UK. This research aims to answer a number of key questions which will inform the shingles vaccination policy in the UK
Firstly, this research will find out how common shingles and important complications are; including possibly risks of heart attack. Secondly, it is well known that people with suppressed immune systems, e.g. from chemotherapy, are at increased risk of shingles. However we know very little about the impact of common disorders such as obesity and diabetes which may increase risks of shingles and related problems. Thirdly, this study will provide important information about patterns of use of shingles treatments and their effectiveness in clinical practice in the UK. Finally I will focus on the benefit of shingles vaccination in the population.
To answer these questions, I will use a very large general population cohort in the UK. This is a novel timely study of particular relevance to the NHS in the early stages of introducing a large scale HZ vaccination program.

Background

Herpes zoster (HZ) is a common disease. The lifetime risk for HZ is between 25% and 35% rising to almost 50% among people surviving to aged 85 years or greater, and it is estimated that there are more than 88,650 incident cases annually in the UK among immunocompetent people aged greater than 60 years. [1-3]

Common comorbidities

Age is the major predictor of HZ incidence; this is believed to be due to waning specific cell mediated immunity. In specific profoundly immunosuppressed high risk groups, HZ incidence rates and complications are increased, e.g. HIV infection, immunosuppressive therapies for cancer/post-transplant and specific autoimmune diseases (e.g. inflammatory bowel disease and Wegener's granulomatosis).[4-7] Risks of HZ and its sequelae could also be increased among those with common disorders of major public health importance possibly associated with lesser degrees of immunosuppression, such as diabetes mellitus, obesity and chronic obstructive pulmonary disease (COPD).[8, 9] Despite the importance of these conditions, HZ natural history has not been adequately studied in these groups. Diabetes has been identified as a possible risk factor for HZ in a case-control study from Israel.[10] A recent study from Taiwan has also suggested that individuals with COPD may be at increased risk of HZ.[11] Obesity has not been previously studied in relation to HZ. Improved understanding of HZ among people with impaired cell mediated immunity is crucial to establish potential benefits and risks of vaccination.[12]

Consequences of HZ

The most common overall complication of HZ is post-herpetic neuralgia (PHN), affecting 30% of individuals with HZ aged 80-84 years in the UK in routine practice and resulting in prolonged morbidity.[13] However, a range of other severe sequelae can occur following HZ, and the epidemiology of these outcomes is poorly understood. Specific areas requiring study in a population-based study include the incidence of serious events (encompassing cardiovascular and other sequelae), hospitalisation and all cause mortality. Work undertaken by my mentor established that acute systemic infections in adults are associated with more than a three-fold transient increased risk of stroke in the first few days following infection and more than a two-fold increased risk of myocardial infarction.[14, 15] The effect of specific infections has been less explored; HZ could plausibly result in an increased risk of cardiovascular outcomes. Work is currently being undertaken by our group (ISAC 10_089) to determine if

there is an association between herpes zoster and stroke. The incidence of myocardial infarction following HZ has not been investigated. Overall mortality may also be increased following HZ, e.g. related to pneumonia, venous thromboembolism and major cardiovascular events; this has not been specifically studied. Current UK mortality estimates are based on two sources: cause of death from death certificates (which may underreport HZ) and deaths during hospitalization which relate to short-term mortality only.[16]

Antiviral therapy

The efficacy of antivirals for treating acute HZ has been demonstrated in randomized controlled trials (RCTs). [17] No study has described overall patterns of use, effectiveness and adverse outcomes of antivirals for HZ in UK clinical practice. These studies will provide information needed about absolute event probabilities to inform risk- and cost-benefit studies.[18]

Herpes zoster vaccine

The development of a HZ vaccine has been a major breakthrough in this field. Oxman *et al* demonstrated a 51% reduction in episodes and a 66% reduction in post herpetic neuralgia in a US randomized controlled trial (RCT) of HZ vaccine.[19] It is unclear what the impact of HZ vaccination has on other HZ-associated complications. No stratification by comorbidity has been published showing HZ vaccine efficacy or side effects in individuals with mild to moderate immunosuppression. These individuals may have greater risks of HZ infection and adverse outcomes and may benefit from earlier vaccination, analogous to UK influenza vaccination policy.[20] This group may have also increased risks of vaccine adverse effects.

Routine HZ vaccination was introduced in the US for immunocompetent individuals aged ≥60 years in 2006.[19] A similar program is planned in the UK for people aged ≥70 years. HZ and varicella vaccines are currently not recommended in severe immunosuppression. Varicella vaccine has been used in children with leukaemia, HIV and following transplants.[21, 22] No similar published experience exists for HZ vaccine, the dose of which is 14 times higher than varicella vaccine.

Further study is required to understand the natural history of HZ particularly in groups with common comorbidities and possible impaired cell mediated immunity. The proposed study combines cohort, nested case-control and self-controlled case series studies using the UK General Practice Research Database (GPRD) to study HZ outcomes, the impact of mild to moderate immunosuppression, patterns of use and effectiveness of antivirals and the benefit of HZ vaccination. Looking at GPRD data allows study of absolute outcomes in a large real population, rather than clinical trial populations. Study of the impact of vaccination on HZ incidence and sequelae may be monitored by the Health Protection Agency but its impact on less established HZ complications are likely to be outside routine surveillance and will require further study.

What is not known?

- What is the recent incidence of HZ in the UK, including among immunocompromised individuals?
- What is the incidence of serious conditions e.g. myelitis, encephalitis, myocardial infarction and all cause mortality after incident HZ?
- Do novel risk factors associated with some immunosuppression, such as diabetes, obesity and COPD, increase the risk of incident HZ and complications?
- What are the patterns of use and effectiveness of HZ antivirals in clinical practice in the UK?
- How effective is HZ vaccination at preventing HZ and complications in pragmatic use?
- Should systemic antivirals and vaccination be considered at younger ages for treatment or prevention of HZ respectively in people with diabetes, obesity and COPD?

Aims

This project has two overall aims. Firstly, to update incidence estimates of HZ, the frequency of serious health outcomes following HZ and to identify new risk factors for HZ and severe sequelae. The second

aim is to estimate the effect of HZ vaccination and antiviral therapy on the natural history and complications of HZ.

The specific study objectives are:

1. To obtain up-to-date detailed estimates of the incidence of HZ in the UK;
2. To identify novel risk factors associated with increased incidence of HZ, namely comorbidities associated with some degree of immunosuppression such as diabetes, chronic obstructive pulmonary disease and obesity;
3. To determine a) the frequency of serious medical conditions following HZ infection including myocardial infarction, post-herpetic neuralgia, myelitis, encephalitis, hospitalizations, all cause and cause-specific mortality , and b) to determine to what extent individuals with HZ are at increased risk of specific outcomes;
4. To identify determinants of serious sequelae among individuals with HZ, including:
   (a) Age, sex;
   (b) Comorbidities associated with some degree of immunosuppression such as diabetes, chronic obstructive pulmonary disease and obesity;
5. To describe patterns of use of antiviral therapy for HZ and to determine the effectiveness of antivirals in preventing severe sequelae of HZ in a routine clinical setting.
6. To determine the effect of HZ vaccination in everyday use on HZ natural history and complications in the UK following introduction of the vaccine.

Study type

Hypothesis generating and testing

Plan of investigation, study design and study population

Identification of incident herpes zoster group

Incident HZ individuals will have been registered with their practice for at least 12 months and will be identified by the presence of diagnostic Read/OXMIS codes in GPRD. Incident HZ will be defined as an episode of HZ without evidence of HZ for at least two years previously.

The GPRD has a number of key linkages which are highly useful for this study as follows:

a) Hospital Episode Statistics (HES)

HES contains details of all people admitted to NHS hospitals in England; the HES-GPRD link provides information on patients hospitalised from 1997 onwards.

b) Office of National Statistics (ONS)

ONS mortality data are linked to GPRD and record cause of death from death certificates

c) Myocardial Infarction Audit Project (MINAP)

MINAP is the United Kingdom's national register of acute coronary syndromes which includes all 230 hospitals in England and Wales.

All analyses will be carried out using Stata 10 (Stata Corp., College Station, TX, USA). Descriptive studies will provide updated HZ incidence and mortality data. These will be followed by a nested case control study to identify novel risk factors for incident zoster and a series of cohort studies to determine risk factors for HZ sequelae. Finally cohort studies will be used to study the effectiveness of HZ vaccination in the UK population.

1.Descriptive analyses (Objectives 1,3a, and 5)

Analysis Incidence and mortality rates will be estimated using GPRD age and gender-specific denominators. Incidence and mortality rates will be standardized to the European Standard population (2000). Antiviral usage patterns will be assessed by year, age, gender, region, socioeconomic status, diagnosis and underlying comorbidity.

Outcomes Incidence of HZ by age, gender, region, socioeconomic status and over time (2000-2010 in GPRD), mortality at 0-3, 4-6 and 7-12 months after HZ. Antiviral usage patterns and adverse events.

2. Identifying novel risk factors for developing HZ (Objective 2)
Study design Nested case control study
Cases and controls Individuals with incident HZ and age, gender and practice-matched controls with no history of HZ.
Exposures Diabetes, chronic obstructive pulmonary disease and obesity.
Covariates Age, gender, immunosuppression (HIV, malignant neoplasms, multiple myeloma, sickle cell disease, alcohol dependence syndrome, chronic liver or kidney disease, cirrhosis, nephrotic syndrome, organ/tissue transplant and immunosuppressive medications).
Analysis Conditional logistic regression will be used to study the effect of exposures on HZ incidence adjusting for relevant covariates.
Outcomes Adjusted odds ratios for HZ

3. Determining the increased risk of specific conditions after HZ (Objective 3b)
Study designs: Cohort study and self-controlled case series (SCCS) studies
Exposed and unexposed: i) Cohort study: individuals with and without HZ, matched for age, sex and practice; ii) SCCS studies: within-person comparison of exposed periods (following HZ) and non-exposed periods in individuals with HZ with specific outcomes.
Covariates: Age, and (for cohort) gender, smoking, atrial fibrillation, body mass index, hypertension, diabetes, hyperlipidaemia.
Analyses: Poisson regression will be used to model rates of events following incident episodes of HZ, adjusting for relevant covariates and examining whether any increased risk is modified by prior receipt of antivirals. For SCCS analyses, age-adjusted relative incidence of events in defined intervals after HZ relative to all other observed time periods will be derived.
Outcomes Adjusted rate ratios for myocardial infarction, myelitis, encephalitis, hospitalization within 180 days of incident HZ and death.

4. Investigating factors that increase the risk of sequelae among individuals with HZ (Objective 4)
Study design: Cohort study of all people with incident HZ
Exposures of interest Specific exposures to be assessed include diabetes, chronic obstructive pulmonary disease, obesity and antiviral medications.
Covariates Age, gender, other disorders associated with immunosuppression (objective 2); comorbidities, antivirals and duration of follow up.
Analysis Cox regression will be used to compare hazard ratios for outcomes in exposed individuals compared to unexposed adjusting for any relevant covariates.
Outcomes Incidence rates and hazard ratios for serious complications including post-herpetic neuralgia, myocardial infarction, myelitis, encephalitis, hospitalization within 180 days of incident HZ and death.

5. The effect of HZ vaccination on natural history of HZ (Objective 6)
Study design Cohort study; Individuals aged ≥70 years (UK) after introduction of HZ vaccination.
Exposed and unexposed groups Exposed individuals have had HZ vaccination; unexposed individuals will not have had the HZ vaccine.
Covariates See objective 4.
Analysis Incidence and hazard rates for HZ and complications in vaccinated and unvaccinated individuals. Cox regression will model rates of events comparing these groups. Propensity scores will allow for differences between vaccinees and not vaccinated.

Outcomes Incidence and hazard rate ratios for outcomes identified in objective 3

Power and sample size calculations

There are 126,599 cases of HZ in the GPRD from 2000 to 2010 with five years total follow up.
Novel risk factors for HZ If the true odds ratio for disease in exposed subjects, relative to unexposed subjects is 1.5, we will need to study 11152 HZ individuals with 1 matched control per case to be able to reject the null hypothesis that this odds ratio equals 1 with probability (power) 0.8 at the 5% level of significance, allowing for multivariable analysis.
Factors increasing the risk of HZ sequelae We need 2059 individuals with both COPD and HZ, or 34,317 HZ patients in total (assuming 6% of the cohort have COPD) to have 80% power to detect a hazard ratio of 1.5 for myocardial infarction in exposed individuals with COPD at the 5% level of significance, allowing for multivariable analysis.
Vaccine effectiveness 9843 exposed (vaccinated) individuals and equivalent numbers of unvaccinated individuals are required to have 80% power to detect a 50% reduction in incident HZ at the 95% level of significance. Assuming 3% of the GPRD population in the eligible age groups are vaccinated (n=14460), this should allow >99% power at the 95% level of significance to assess the effectiveness of the vaccine.

Limitations

Validation work on HZ has not been done in previous GPRD studies and documentation in GP records of clinical presentation or severity of HZ is likely to be limited. The key differential diagnosis for HZ is recurrent herpes simplex, which occasionally presents with a dermatomal distribution. Viral culture and PCR are highly unlikely to have been performed in routine practice and would be cost prohibitive to measure in a large population-based study. However, HZ is usually a straightforward clinical diagnosis based on classical clinical presentation. Excluding cases with recurrence intervals less than two years should exclude misclassified cases whilst not excluding immunosuppression-related HZ recurrence. A range of sensitivity analyses will be undertaken for all objectives, excluding recurrent cases of HZ with different intervals. The propensity score method will be used to address chanelling bias.

Patient or user group involvement

When I did my PhD in Nottingham, I involved service users in the development and selection of tools to measure exposures and outcomes and to disseminate study findings in conjunction with the Nottingham support group for carers of children with eczema. For this study, I will build on this expertise and work with a panel of individuals with a history of herpes zoster. A panel of people with a history of herpes zoster led by an experienced consumer, will advise on planning further studies and dissemination of results

Plans for disseminating and communicating study results

Study results will be widely disseminated by presenting study findings at scientific meetings and by publishing in leading scientific journals.

Amendment 1 (APPROVED: 9 May 2012, protocol number 11_028A2R)

We are now requesting to extract all COPD patients in GPRD to study zoster incidence and risk among COPD patients in greater detail.

This will allow the following additional aim:

To look in greater detail among COPD patients:

- **To calculate incidence of zoster among COPD patients.**
- **To determine if the risk of zoster varies by COPD treatment group.**
- **To determine if there is an increased risk of HZ after COPD exacerbation.**

Study Types:
Incidence of zoster among COPD patients
(as with study type 1 outlined above)

Risk of zoster by COPD treatment group
Study Design: Nested Case control study
Cases and controls: Cases are COPD patients with incident HZ; controls are patients with no history of HZ who are age, gender and practice-matched to COPD cases.
Exposures Short-term treatment for COPD (treatment given three months before index date) and long-term treatment
Covariates Age, gender, immunosuppression (HIV, malignant neoplasms, multiple myeloma, sickle cell disease, alcohol dependence syndrome, chronic liver or kidney disease, cirrhosis, nephrotic syndrome, organ/tissue transplant and immunosuppressive medications), moderate immunosuppression (Diabetes, chronic obstructive pulmonary disease and obesity).
Analysis Conditional logistic regression will be used to study the effect of exposures on HZ incidence adjusting for relevant covariates.
Outcomes Adjusted odds ratios for HZ

Is there an increased risk of HZ after COPD exacerbation?
Study designs: Cohort study and self-controlled case series (SCCS) studies
Exposed and unexposed: i) Cohort study: COPD individuals with and without COPD exacerbations, matched for age, sex and practice; ii) SCCS studies: within-person comparison of exposed periods (within one month following COPD exacerbation) and non-exposed periods in COPD patients with HZ.
Covariates: Age, and (for cohort) gender, immunosuppression (HIV, malignant neoplasms, multiple myeloma, sickle cell disease, alcohol dependence syndrome, chronic liver or kidney disease, cirrhosis, nephrotic syndrome, organ/tissue transplant and immunosuppressive medications), moderate immunosuppression (Diabetes, chronic obstructive pulmonary disease and obesity).
Analyses: Poisson regression will be used to model rates of zoster following COPD exacerbation, adjusting for relevant covariates. For SCCS analyses, age-adjusted relative incidence of zoster in defined intervals after COPD exacerbations relative to all other observed time periods will be derived.
Outcomes Adjusted rate ratios for myocardial infarction, myelitis, encephalitis, hospitalization and death within 180 days of incident HZ.

Amendment 2

- Aim 2: A wider range of risk factors for zoster will be assessed.
Recent research has implicated a number of clinical conditions and lifestyle factors as risk factors for zoster including diabetes mellitus[23, 24], chronic obstructive pulmonary disorder (COPD) [24, 25], chronic kidney disease (CKD) [26-28], asthma[29] and depression [30, 31] all of which may be associated with cell-mediated immune suppression.[32-37] It has also been postulated that obesity leads to a degree of cell mediated immune suppression.[38] However, there has been a lack of large, highly powered studies using a systematic approach looking at a wide range of risk factors. Furthermore, adjustment for confounders has often been inadequate and studies have not quantified the population impact of these risk factors. Given the limited current evidence on a wider range of risk factors than we originally planned to look at, all of which are plausibly associated with cell-mediated immunity, we would like to broaden our analysis to include all of the risk factors mentioned above. The above issues and the proposed change arose from discussions between the PhD student leading this study, and the supervisors and advisory group. Additionally, we wish to conduct a focused analysis to look at the effect of statin use on zoster risk. This will be done as an LSHTM MSc summer dissertation (supervised by Krishnan Bhaskaran), and is in response to a recent study (Antonou et al, Clin Infect Dis 2014, 58:350-6), suggesting an increased risk of zoster in statin patients, We felt that the dataset we have developed for the main study would be ideally suited to looking at this research question, and that this would make an interesting and useful training project for an MSc Epidemiology student. For the MSc project, the student will use the same case-control design, and will be able to adjust for the range of covariates already extracted.

- Aim 4: As well as identifying risk factors for post-herpetic neuralgia (PHN) in zoster patients, we will also look at risk factors in the general population
In our original plan (part 4), we specified a cohort analysis to look at risk factors for developing PHN in a cohort of patients with zoster. After further discussions among the PhD advisory group guiding this study, we would now like to also look at risk factors for PHN in the general population, by re-running the model developed in objective 2 (risk factors for zoster), restricted to cases of zoster who go on to get PHN and their non-zoster controls. This analysis will address the question “what are the risk factors in the general population for contracting ‘complicated zoster ‘, i.e. zoster complicated by PHN”, which is of relevance to informing zoster vaccination policy. The analysis will be stratified by whether PHN patients received antiviral therapy; this is because antivirals may themselves modify the risk of PHN. It will be stated *a priori* that we do not intend to measure the effectiveness of antivirals; this is due to confounding by indication (patients with severe zoster are more likely to get antivirals and more likely to get PHN).

Copyright, open access, and permission to reuse

Copyright for authors

Since January 2000, *The BMJ* has not asked authors of journal articles to assign us their copyright. Authors (or their employers) retain their copyright in the article. All we require from authors is an exclusive licence (or, from government employees who cannot grant this, a non-exclusive licence) that allows us to publish the article in *The BMJ* (including any derivative products) and any other BMJ products (such as the *Student BMJ* or overseas editions), and allows us to sublicence such rights and exploit all subsidiary rights.

We ask the corresponding author to grant this exclusive licence (or non-exclusive for government employees) on behalf of all authors by reading our licence and inserting in the manuscript on submission the following statement:

"The Corresponding Author has the right to grant on behalf of all authors and does grant on behalf of all authors, a worldwide licence to the Publishers and its licensees in perpetuity, in all forms, formats and media (whether known now or created in the future), to i) publish, reproduce, distribute, display and store the Contribution, ii) translate the Contribution into other languages, create adaptations, reprints, include within collections and create summaries, extracts and/or, abstracts of the Contribution, iii) create any other derivative work(s) based on the Contribution, iv) to exploit all subsidiary rights in the Contribution, v) the inclusion of electronic links from the Contribution to third party material where-ever it may be located; and, vi) licence any third party to do any or all of the above."

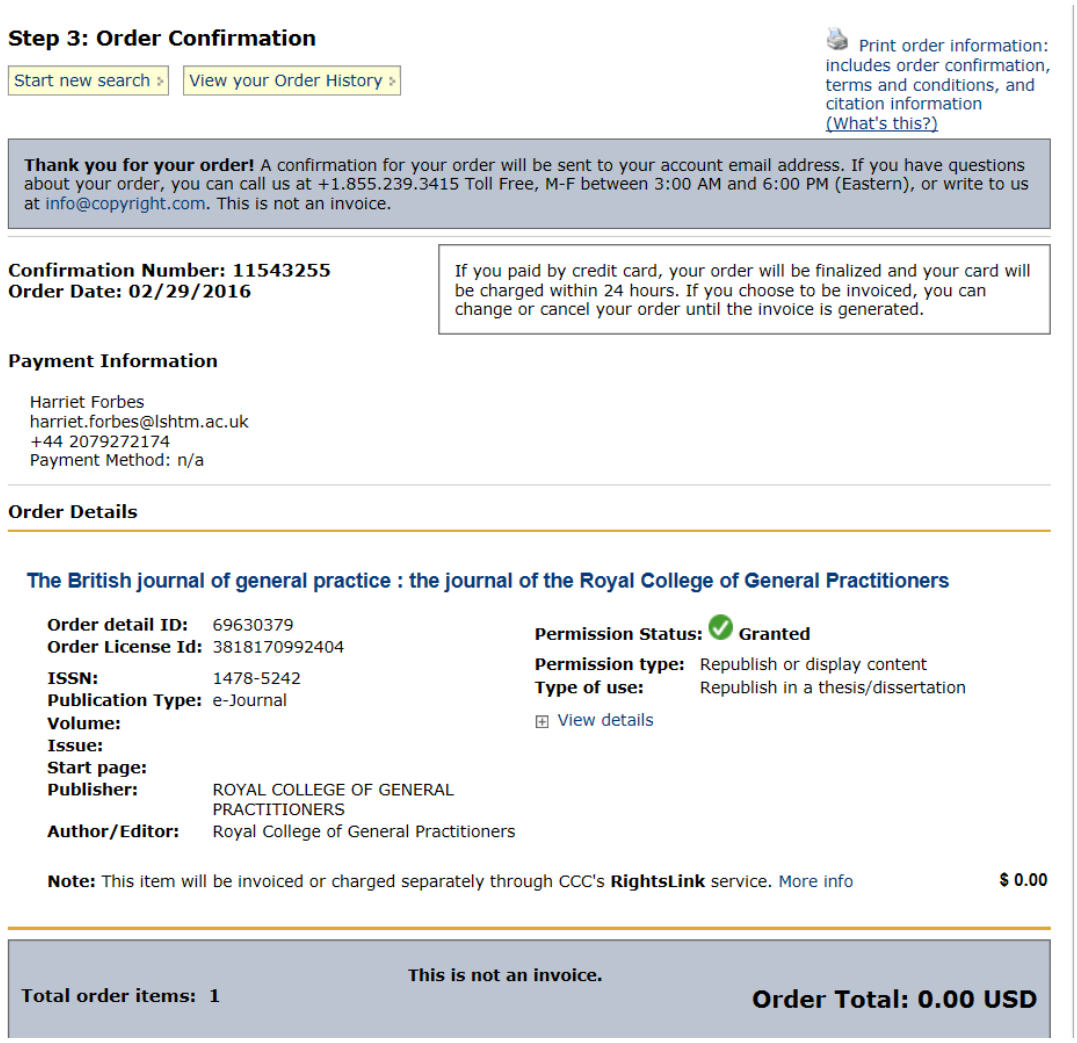
This licence allows authors to use their own articles for their own non-commercial purposes without seeking permission from us. Only if the use is commercial do we need to know about it. In addition, we will pay authors a royalty on certain commercial uses that we negotiate.

Permissions for authors

Thus authors may use their own articles for the following non-commercial purposes without asking our permission (and subject only to acknowledging first publication in *The BMJ* and giving a full reference or web link, as appropriate).

- Posting a pdf of their own article on their own personal or institutional website, for which no charge for access is made.
- Making a reasonable number of copies for personal or non commercial professional use. This includes the contributor's own teaching purposes.
- Republishing part or all of the article in a book or other publication edited by the author (except for multiple contributions in the same book or publication, for which permission needs to be sought
- Using individual figures or tables or extracts of text (up to 250 words) in other publications published by a third party.
- Using the article in a course pack or compilation (whether paper or electronic) in the authors' institution. This does not apply if a commercial charge is made for the compilation or training programme.

Article entitled, “Prescription of antiviral therapy after herpes zoster in general practice: who receives therapy?”, published in the BJGP (presented in chapter 5).



Step 3: Order Confirmation

Start new search | View your Order History

Print order information: includes order confirmation, terms and conditions, and citation information (What's this?)

Thank you for your order! A confirmation for your order will be sent to your account email address. If you have questions about your order, you can call us at +1.855.239.3415 Toll Free, M-F between 3:00 AM and 6:00 PM (Eastern), or write to us at info@copyright.com. This is not an invoice.

Confirmation Number: 11543255
Order Date: 02/29/2016

If you paid by credit card, your order will be finalized and your card will be charged within 24 hours. If you choose to be invoiced, you can change or cancel your order until the invoice is generated.

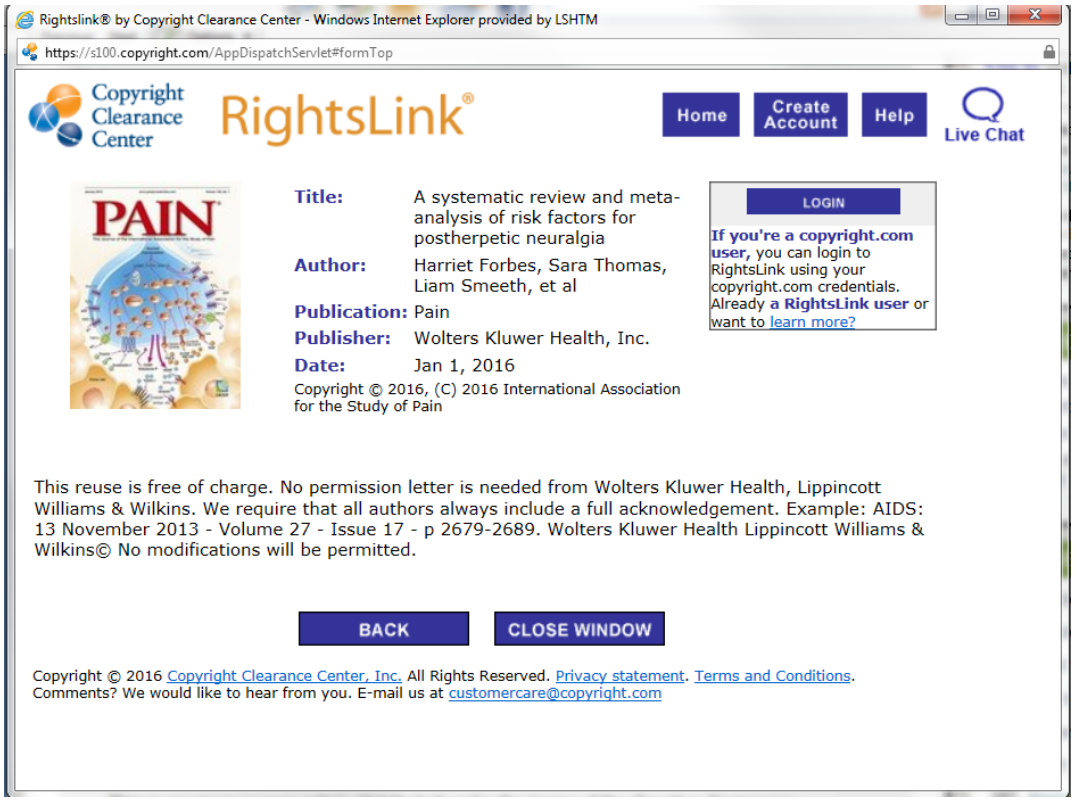
Article entitled, “A systematic review and meta-analysis of risk factors for postherpetic neuralgia”, published in the journal PAIN (presented in chapter 7).



Appendix III: Section A of published appendices from BMJ zoster case control study

The zoster case control study published in the BMJ (chapter 4) has an appendices, for which section A was not included in the main PhD, as its content was described in chapter 3, "Data sources and variable definitions". For transparency, this section of the appendices appears below.

A: Further detail on defining risk factors

We assessed three autoimmune conditions; *rheumatoid arthritis, systemic lupus erythematosis and inflammatory bowel disease.* These were defined as a diagnosis prior to the index date. Chronic obstructive pulmonary disorder patients were defined as those with a diagnosis of chronic obstructive pulmonary disorder, including chronic bronchitis and emphysema, prior to the index date and ≥35 years at first chronic obstructive pulmonary disorder diagnosis). Asthma patients were those with an asthma diagnosis before the index date and an asthma-related prescription [short and long-acting beta-2 agonists and antimuscarinics, inhaled corticosteroids, cromoglycates and nedocromil, theophyllines, leukotriene receptor agonists and omalizumab] within 12 months prior to the index date; patients with a chronic obstructive pulmonary disorder diagnosis ever in their medical history were not classified as asthmatic). Chronic kidney disease patients were those with a diagnosis of mild, moderate or severe chronic kidney disease, kidney transplant or kidney dialysis, any time prior to the index date. Depression was defined as having a diagnosis or symptom of depression (such as “feeling depressed” or “sad mood”) or within one year prior to the index date; symptoms were included due to the trend post-2004 of using symptom rather than diagnosis codes in UK primary care[122].

To define diabetes we required a definite diabetes diagnosis, or a possible diabetes code [e.g. self- monitoring of blood glucose] with a subsequent diabetes-specific prescription [insulin or oral anti-diabetics], or ≥2 diabetes drug prescriptions prior to the index date; gestational diabetes and drug-induced diabetes were excluded. We also used age at first diagnosis, age at first treatment and treatment received to classify patients into Type 1 or 2 diabetes. Patients were categorised as type 1 or type

2 diabetes where possible. Distinguishing between type 1 and type 2 diabetes is not always possible from diabetes codes as patients are frequently given a non-specific code. Furthermore, where type of diabetes is assigned, it has been found to be unreliable.[111] Therefore we chose not to use this information, but instead use age at first diagnosis, age at first treatment and treatment received to classify diabetes type, as in previous Clinical Practice Research Datalink studies.[112 113] Type 1 was assigned where; age at first diagnosis was ≤35 years and treatment ever was exclusively insulin, or patients received at least two insulin prescriptions ≤35 years, but had no diabetes diagnosis. Type 2 was assigned where; age at first diabetes diagnosis was >35; or patients received exclusively oral anti-diabetic's >35 years. Patients with age at diagnoses >35 but treated exclusively with insulin and those not fitting into these categories were assigned as "Unknown type".

Calculating duration of prescriptions in the Clinical Practice Research Datalink and identifying high-dose oral corticosteroids

In order to identify relevant prescriptions, it was necessary to calculate the duration of individual prescriptions prior to the index date.

Variables available

The Clinical Practice Research Datalink does not provide researchers with duration and dose for individual prescriptions. Instead, these must be generated using information from other variables. On prescribing, general practitioners select the drug and can enter information on quantity (of tablets or inhalers prescribed), number of days, number of packs, pack type (number of tablets per pack or number of puffs per inhaler) and also enter free text. The free text field contains the actual prescribing information; in other words how many tablets, grams, milligrams or puffs the patient should take each day. To utilize this prescribing information, the Clinical Practice Research Datalink developed an algorithm to derive a numerical value from the free text and provide this to researchers;[105] this is referred to within the Clinical Practice Research Datalink as the *numeric daily dose (NDD)*. The dose (in milligrams or micrograms) per tablet or puff is typically contained in the product name.

The completeness of each variable is described in table A1 below.

Table A1: Completeness of variables used to identify duration and dose of corticosteroid prescriptions before cleaning.

		% complete		
Description	**Variable name**	**Oral corticosteroids**	**Other immunosuppressive therapy**	**Inhaled corticosteroids**
Quantity[1]	Qty	99	99	99
Number of days	numdays	9	7	8
Number of packs	numpacks	2	3	1
Pack type[2]	packtype	<0.5	4	52
Dose in mg	*extract from product name*	100	100	100
Numeric daily dose	ndd	67	67	81

[1] For ICS prescriptions quantity referred to number of inhalers, otherwise quantity referred to number of tablets
[2] For ICS prescriptions pack type referred to numbers of puffs per inhaler, for OCS prescriptions pack type was largely missing

Data cleaning

We carried out a series of data-checking and data-cleaning tasks including; checking the accuracy of NDD for the 500 most commonly occurring free-texts; extracting data for pack type from other variables (eg quantity variable); checking the clinical and referral records of 20 randomly selected patients to check the duration and dose was consistent with the clinical picture; excluding implausible values of quantity and NDD.

As NDD was not always available it was necessary to impute missing data. A "hot-deck" style imputation method was adopted, which replaced missing data with comparable data from the same set. An algorithm was developed which reviewed each oral corticosteroid and other immunosuppressive therapy record and imputed missing values. An extra binary variable for quantity was created, categorising quantity about the median (42 tablets for steroids, 36 for other immunosuppressants) into low and high. If a patient had any other record with the same quantity and dose, the

median NDD among those records was used where NDD was missing. If a patient had no recorded NDD but had any other record of the same dose and quantity as a binary variable, the median NDD among those records was used. If a patient did not have a recorded NDD or quantity, but had records for the same dose, then the median NDD among those records was used. If there was no record of NDD, dose or quantity, but there were other patients in the dataset in the same 5-year age band, of the same gender, with the same dose and quantity, the using median NDD for those records was used. Finally, if none of the above were possible, patients in the dataset in the same 5-year age band, of the same gender, with the same dose and quantity as a binary variable, the median NDD among these records was used.

Pack type for inhaled corticosteroids was imputed using the most common pack type for the quantity and dose of each prescription. Where NDD was missing for inhaled corticosteroids, the median value of 4 puffs per day was used.

Calculating duration and dose

Using this information we calculated duration of oral corticosteroid or other immunosuppressive therapy prescription as follows: total quantity of tablets prescribed / NDD. Duration of inhaled corticosteroids was calculated: (quantity x pack type)/NDD. Dose was calculated as follow; NDD x dose per tablet or puff.

Algorithm to select smoking, alcohol and BMI status.

Data were derived from medical Read codes and data from the additional details file. Read codes classifying patients by BMI category are very rarely recorded, therefore were not used. Where patients had multiple recordings, the nearest status in the

period -1y to +1month from index was taken (best); if not available, then the nearest in the period +1month to +1y after index was taken (second best); if not available, then the nearest before -1y from index was taken (third best); if not available, then take nearest after +1y from index was taken (least best).

Appendix IV: Section e-I of published appendices from Neurology PHN cohort study

APPENDIX

e-1: Further details on definitions of risk factors

Severe Immunosuppression

Our models included severely immunosuppressive conditions determined to be vaccine contraindications by the Advisory Committee on Immunization Practices,[1] namely recent history (<2 years before zoster diagnosis) of leukaemia or lymphoma, or any history of HIV, hematopoietic stem cell transplantation, myeloma or 'other unspecified cellular immune deficiencies' (e.g. pancytopenia). Use of immunosuppressive therapy was also included; all relevant prescriptions prior to zoster diagnosis were extracted, prescription duration was calculated (using data on quantity of tablets prescribed and numeric daily dose). Oral corticosteroid exposure was defined as a 14-day course of high-dose (≥20 mg/day) oral corticosteroids in the month prior to zoster diagnosis. Exposure to other immunosuppressive therapies in the month prior to the zoster diagnosis was included as an additional covariate.

Other comorbidities

We assessed three autoimmune conditions; *rheumatoid arthritis, systemic lupus erythematosis and inflammatory bowel disease.* These were defined as a diagnosis prior to the zoster diagnosis.

Chronic obstructive pulmonary disorder patients were defined as those with a diagnosis of chronic obstructive pulmonary disorder, including chronic bronchitis and emphysema, prior to the zoster diagnosis and ≥35 years at first chronic obstructive pulmonary disorder diagnosis).

Asthma patients were those with an asthma diagnosis before the zoster diagnosis and an asthma-related prescription [short and long-acting beta-2 agonists and antimuscarinics, inhaled corticosteroids, cromoglycates and nedocromil, theophyllines, leukotriene receptor agonists and omalizumab] within 12 months prior to the zoster diagnosis; patients with a chronic obstructive pulmonary disorder diagnosis ever in their medical history were not classified as asthmatic.

Chronic kidney disease patients were those with a diagnosis of mild, moderate or severe chronic kidney disease, kidney transplant or kidney dialysis any time prior to the zoster diagnosis.

Depression was defined as having a diagnosis or symptom of depression (such as "feeling depressed" or "sad mood") within one year prior to the zoster diagnosis; symptoms were included due to the trend post-2004 of using symptom rather than diagnosis codes in UK primary care.[2]

To define *diabetes* we required a definite diabetes diagnosis, or a possible diabetes code [e.g. self- monitoring of blood glucose] with a subsequent diabetes-specific prescription [insulin or oral anti-diabetics], or ≥2

diabetes drug prescriptions prior to the zoster diagnosis; gestational diabetes and drug-induced diabetes were excluded. We also used age at first diagnosis, age at first treatment and treatment received to classify patients into Type 1 or 2 diabetes. Distinguishing between type 1 and type 2 diabetes is not always possible from diabetes codes as patients are frequently given a non-specific code. Furthermore, where type of diabetes is assigned, it has been found to be unreliable.[3] Therefore we chose not to use this information, but instead use age at first diagnosis, age at first treatment and treatment received to classify diabetes type, as in previous Clinical Practice Research Datalink studies.[4 5] Type 1 was assigned where; age at first diagnosis was ≤35 years and treatment ever was exclusively insulin, or patients received at least two insulin prescriptions ≤35 years, but had no diabetes diagnosis. Type 2 was assigned where; age at first diabetes diagnosis was >35; or patients received exclusively oral anti-diabetics's >35 years. Patients with age at diagnoses >35 but treated exclusively with insulin and those not fitting into these categories were assigned as "Type not specified".

Recent cancer was defined as *any* cancer diagnosed in previous year (excluding leukaemia and lymphoma previously categorised as severely immunosuppressive).

Health behaviours features of acute zoster

For *smoking*, data were derived from medical Read codes and data from the additional details file. For *BMI*, only data from the additional details files was used, as Read codes classifying patients by BMI category are very rarely recorded. Where patients had multiple recordings, the nearest status in the period -1y to +1month from zoster diagnosis date was taken (best); if not available, then the nearest in the period +1month to +1y after zoster diagnosis date was taken (second best); if not available, then the nearest before -1y from zoster diagnosis date was taken (third best); if not available, then take nearest after +1y from zoster diagnosis date was taken (least best).

Site of acute zoster was identified from the presence of specific zoster diagnostic codes. Some Read and ICD codes specify the site of zoster (such as, "Herpes zoster with dermatitis of eyelid"); codes indicating site within 12 months after first diagnosis were used. In line with a previous study identifying ophthalmic zoster in CPRD, we also defined ophthalmic zoster as patients with nonspecific zoster, plus a diagnosis of, or treatment for, acute eye infection (such as keratitis or conjunctivitis) within 2 weeks of zoster onset or from records of first-ever specific chronic eye conditions known to be associated with zoster (such as, conjunctival scarring or episcleritis), within 3 months after zoster onset.[6]

Antiviral use at acute zoster was identified through prescription of acyclovir, valaciclovir or famciclovir within 7 days from zoster diagnosis.

Possible misdiagnosis of herpes simplex as herpes zoster

Of the 119,413 cohort, 1586 (1.6%) patients had a further zoster code 90-365 days after their first zoster. Of these 215 (13.6%) had a PHN medication or a PHN diagnostic code, and in the main analysis these were

categorised as PHN. However, the other 1371 patients had a zoster code without medications or codes suggesting PHN. There were three possible explanations for these patients. The first is that they were recurrent zoster; however this is very rare in immunocompetent patients, who made up 96% of the group. The second is that these are poorly coded PHN patients, however it seems unlikely that no PHN prescriptions would be given. The third, and perhaps most plausible explanation is that these patients were misdiagnosed herpes simplex cases. Herpes simplex is known to recur more frequently than zoster and can, albeit rarely, present with dermatomal distribution similar to herpes zoster. [7] Further to this, half of the patients were prescribed an antiviral at their later zoster diagnosis, which may further indicate misdiagnosis of herpes simplex. Therefore as a sensitivity analysis we excluded all 1586 patients with a further zoster code following first zoster diagnosis.

Risk factors we are unable to assess included: physical trauma[8] or surgical intervention at site of zoster,[8] genetic factors, ethnicity and functional status[9] (appendix section A-I for more details on these variables).

Appendix V: Code lists

Code lists are provided below, and listed alphabetically:

Alcohol
Asthma diagnosis
Asthma therapy
CKD
COPD
Depression
Diabetes diagnosis
Diabetes treatments
Epilepsy
Hematopoietic stem cell transplantation (HSCT)
Herpes Zoster
HIV
Hypothyroidism
IBD
Leukaemia
Lymphoma
Myeloma
Neuropathy
Oral corticosteroids
Other Immune Disorders (OID)
Other immunosuppressive therapies
PHN diagnosis
PHN - Neuralgia diagnosis
PHN - Neuropathic pain
PHN treatment - Anticonvulsants
PHN treatment - Capsaicin Cream
PHN treatment - Lidocaine patches
PHN treatment - Mild painkillers (PKs)
PHN treatment - Tramadol
PHN treatment- Strong painkillers (PKs)
PHN treatment- Tricyclic antidepressants
Rheumatoid arthritis
Smoking
Systemic Lupus Erythematosis

Alcohol

Medical code	Read term	Alcohol status
322	Moderate drinker - 3-6u/day	current drinker

15816	ephedrine hydrochloride tablets 30mg
38136	salbulin mdpi novolizer dry powder inhalation cartridge with device 100micrograms [meda]
14525	salbutamol vortex metered dose inhaler 100micrograms/inhalation
35165	serevent diskhaler inhalation powder 50micrograms [glaxo]
8339	fenoterol hydrobromide complete unit inh
30240	aerolin autohaler cfc free breath actuated inhaler 100micrograms/actuation [3m]
18314	aerocrom syncroner [castlemead]
19649	ventolin rotahaler
13956	ephedrine hydrochloride with chlorphenamine tablets 15mg + 10mg
14382	ephedrine hydrochloride tablets 15mg
34029	salbutamol capsules (for inhalation) 400micrograms
3838	salbutamol 400mcg/beclometh.100mcg r/cap inh
35542	salmeterol inhalation powder blisters with device 50micrograms
3189	salbuvent inh inh
7965	salbutamol respirator solution 5mg/ml
12486	bronchodil aerosol inhaler 500micrograms/dose [viatris]
13575	bambec tablets 20mg [astrazenec]
8267	sodium cromoglicate with salbutamol aerosol inhaler
8149	alupent aerosol refill 750micrograms/inhalation [boeh ingl]
35825	serevent diskhaler (refill) inhalation powder 50micrograms [glaxo]
4222	bricanyl respirator solution 10mg/ml [astrazenec]
7943	orciprenaline tablets 20mg

Asthma therapy

Product Code	Product Name
13307	bricanyl injection 500micrograms/ml [astrazenec]
35725	easyhaler formoterol dry powder inhaler 12micrograms/actuation [orion]
3443	salbutamol spacehaler 100micrograms/inhalation [celltech]
16207	duovent udvs nebuliser solution [boeh ingl]
461	orciprenaline aerosol inhaler 750micrograms/inhalation
25784	atimos modulite cfc free inhaler 12micrograms/actuation [chiesi]
19642	ventolin nebules
12808	fenoterol with ipratropium bromide breath actuated inhaler 100micrograms + 40micrograms/actuation
14483	terbutaline injection 500micrograms/ml
7711	terbutaline spacer inhaler 250micrograms/actuation
7719	ephedrine tablets 30mg
2259	medihaler -iso forte aerosol inhaler [3m]
1436	haymine tablets [chemidex]
10979	ephedrine tablets 15mg
8321	alupent tablets 20mg [boeh ingl]
8872	medihaler -iso aerosol [3m]
35503	salmeterol inhalation powder blisters (refill) 50micrograms
8636	ventolin s/r 8 mg spa
10360	aerocrom aerosol inhaler [castlemead]
14306	formoterol fumarate cfc free inhaler 12micrograms/actuation
14527	bambec tablets 10mg [astrazenec]
3763	terbutaline respules inh
22313	ventmax sr modified release capsules 8mg [opus]
11307	salbutamol with beclometasone aerosol inhaler 100mcg + 50mcg
1794	berotec aerosol inhaler 100micrograms/actuation [boeh ingl]
12563	exirel aerosol inhaler [3m]
2395	salbutamol 2 mg/5ml syr
17696	ventmax sr modified release capsules 4mg [opus]
8522	terbutaline modified release tablet 7.5mg
16625	ventide rotacaps [a & h]
5185	fenoterol aerosol inhaler 200micrograms/actuation
5837	salamol steri-neb unit dose nebulising solution 5mg/2.5ml [numark]
10458	ventolin cr tablets 4mg [a & h]
510	ventolin respirator solution 5mg/ml [a & h]
37470	beclometasone extrafine particle with formoterol cfc free inhaler 100micrograms + 6micrograms/actuation
5898	salamol steri-neb unit dose nebulising solution 2.5mg/2.5ml [numark]
21859	asmaven aerosol inhaler 100micrograms [berk]
10825	terbutaline tablets 5mg
3758	pulmadil aerosol inhaler [3m]
30230	salbutamol breath actuated inhaler 100micrograms/actuation
4908	ventolin rotahaler insufflator [a & h]
12909	salbutamol with ipratropium bromide aerosol inhaler 100micrograms + 20micrograms/actuation
1628	terbutaline refill canister 250micrograms/actuation
7954	bricanyl spacer inhaler [astrazenec]
696	salbutamol modified release capsules 8mg
8508	alupent aerosol inhaler 750micrograms/inhalation [boeh ingl]
3556	beclometasone with salbutamol aerosol inhaler 50micrograms + 100micrograms/inhalation
9805	salbutamol infusion 100micrograms/ml
4541	bricanyl sa tablets 7.5mg [astrazenec]
12144	bambuterol tablets 20mg
4640	bricanyl unit dose nebuliser solution 5mg/2ml [astrazenec]
16577	easyhaler salbutamol dry powder inhaler 200micrograms/actuation [orion]
8511	cam sugar free liquid 4mg/5ml [cambhealth]
12822	salbutamol with ipratropium bromide unit dose nebulising solution 2.5mg + 500micrograms/2.5ml
3534	bricanyl tablets 5mg [astrazenec]
2149	steri-neb salamol 2.5 mg inh
2862	duovent autohaler breath actuated inhaler [boeh ingl]
1975	oxis 6 turbohaler dry powder inhaler 6 micrograms/actuation [astrazenec]
7192	bambuterol tablets 10mg

Asthma therapy

Product Code	Product Name
13273	fluticasone with salmeterol dry powder inhaler 100micrograms + 50micrograms/inhalation
9384	salbutamol modified release capsules 4mg
12042	ventolin cr tablets 8mg [a & h]
5308	terbutaline unit dose nebuliser solution 5mg/2ml
5889	salamol cfc free inhaler 100micrograms/inhalation [kent]
6526	formoterol fumarate capsules (for inhalation) 12mcg
9711	formoterol fumarate dry powder inhaler 6 micrograms/actuation
3764	bricanyl respules (5mg/2ml) 2.5 mg/ml inh
10968	foradil capsules (for inhalation) 12mcg [nov/ciba]
2610	intal compound capsules (for inhalation) [rhone]

7935	maxivent aerosol inhaler 100micrograms/inhalation [ashbourne]
13038	pulvinal salbutamol dry powder inhaler 200micrograms/actuation [chiesi]
4171	ventolin tablets 2mg [a & h]
2020	berotec aerosol inhaler 200micrograms/actuation [boeh ingl]
12994	fluticasone with salmeterol cfc free inhaler 50micrograms + 25micrograms/actuation
13181	easyhaler salbutamol dry powder inhaler 100micrograms/actuation [orion]
13040	fluticasone with salmeterol dry powder inhaler 250micrograms + 50micrograms/inhalation
7017	salbutamol dry powder inhaler 100micrograms/actuation
7953	terbutaline sugar free oral solution 1.5mg/5ml
42886	bricanyl turbohaler dry powder inhaler 500micrograms [astrazenec]
2758	bricanyl refill canister [astrazenec]
3584	bricanyl sugar free oral solution 1.5mg/5ml [astrazenec]
1414	steri-neb salamol unit dose nebulising solution 5mg/2.5ml [ivax]
881	salbutamol tablets 2mg
4665	salbulin cfc free inhaler 100micrograms/actuation [3m]
11410	fluticasone with salmeterol dry powder inhaler 500micrograms + 50micrograms/inhalation
42858	ventolin accuhaler dry powder inhaler 200micrograms/actuation [glaxo]
11046	ipratropium bromide with salbutamol unit dose nebulising solution 500micrograms + 2.5mg/2.5ml
3786	fenoterol with ipratropium bromide aerosol inhaler 100micrograms + 40micrograms/actuation
37432	fostair cfc free inhaler 100micrograms + 6micrograms/actuation [chiesi]
11588	fluticasone with salmeterol cfc free inhaler 125micrograms + 25micrograms/actuation
6462	salbutamol dry powder inhaler 95micrograms
862	salbulin aerosol inhaler [3m]
3994	salbutamol modified release tablet 4mg
3163	salbutamol disc 200micrograms
987	ventolin tablets 4mg [a & h]
7268	serevent evohaler cfc free inhaler 25micrograms/actuation [glaxo]
882	salbutamol capsules (for inhalation) 200micrograms
2869	salbutamol modified release tablet 8mg
1087	asmasal clickhaler dry powder inhaler 95micrograms [focus]
11618	fluticasone with salmeterol cfc free inhaler 250micrograms + 25micrograms/actuation
1974	oxis 12 turbohaler dry powder inhaler 12micrograms/actuation [astrazenec]
1801	ventide aerosol inhaler [a & h]
7133	formoterol fumarate dry powder inhaler 12micrograms/actuation
2490	orciprenaline sugar free oral solution 10mg/5ml
3297	salmeterol disc 50micrograms
860	salbutamol tablets 4mg
957	salamol easi-breathe breath actuated inhaler 100micrograms/actuation [ivax]
1961	volmax tablets 4mg [a & h]
5753	salbutamol disc 400micrograms
10218	budesonide with formoterol dry powder inhaler 100micrograms + 6micrograms/actuation
1957	ventolin nebules unit dose nebulising solution 5mg [a & h]
1960	volmax tablets 8mg [a & h]
2901	alupent sugar free oral solution 10mg/5ml [boeh ingl]
910	serevent diskhaler 50micrograms [glaxo]
1093	salamol aerosol inhaler 100micrograms/actuation [ivax]
2224	serevent accuhaler 50micrograms/actuation [glaxo]
5740	airomir autohaler cfc free breath actuated inhaler 100micrograms/actuation [ivax]
958	ventolin easi-breathe breath actuated inhaler 100micrograms/actuation [a & h]
6938	salmeterol with fluticasone dry powder inhaler 50micrograms + 100micrograms/inhalation

Asthma therapy

Product Code	Product Name
3305	combivent udvs nebuliser solution 2.5ml [boeh ingl]
2851	ventolin rotacaps 200micrograms [a & h]
7013	symbicort turbohaler dry powder inhaler 100micrograms + 6micrograms/actuation [astrazenec]
6746	budesonide with formoterol dry powder inhaler 400micrograms + 12micrograms/actuation
856	ventolin syrup 2mg/5ml [a & h]
942	aerolin autohaler breath actuated inhaler 100micrograms/actuation [3m]
674	ventolin nebules unit dose nebulising solution 2.5mg [a & h]
665	seretide 100 accuhaler dry powder inhaler [glaxo]
2850	salbutamol capsules (for inhalation) 400micrograms
5143	seretide 50 evohaler cfc free inhaler [a & h]
2655	airomir cfc free inhaler 100micrograms/inhalation [teva]
6616	salmeterol with fluticasone cfc free inhaler 25micrograms + 50micrograms/actuation
6780	symbicort turbohaler dry powder inhaler 400micrograms + 12micrograms/actuation [astrazenec]
2722	duovent aerosol inhaler 40micrograms + 100micrograms/actuation [boeh ingl]
1882	ventodisks disc 200micrograms/blister [a & h]
2978	salbutamol dry powder inhaler 200micrograms/actuation
1620	terbutaline aerosol inhaler 250micrograms/actuation
719	salmeterol dry powder inhaler 50micrograms/actuation
5170	salamol cfc free inhaler 100micrograms/inhalation [ivax]
235	bricanyl aerosol inhaler [astrazenec]
5558	salmeterol with fluticasone dry powder inhaler 50micrograms+ 500micrograms/inhalation
4497	ventolin accuhaler 200micrograms/actuation [glaxo]
282	salbutamol sugar free oral solution 2mg/5ml
5942	salmeterol with fluticasone dry powder inhaler 50micrograms + 250micrograms/inhalation
1950	ventodisks disc 400micrograms/blister [a & h]
1952	ventolin rotacaps 400micrograms [a & h]
7270	salmeterol cfc free inhaler 25micrograms/actuation
1711	salbutamol unit dose nebulising solution 5mg/2.5ml
638	seretide 250 accuhaler dry powder inhaler [glaxo]
1630	salbutamol unit dose nebulising solution 2.5mg/2.5ml
3666	seretide 500 accuhaler dry powder inhaler [glaxo]
2152	ipratropium bromide with salbutamol aerosol inhaler 20mcg + 100mcg
5516	salamol easi-breathe cfc free breath actuated inhaler 100micrograms/actuation [ivax]
6796	budesonide with formoterol dry powder inhaler 200micrograms + 6micrograms/actuation
1698	salbutamol breath actuated inhaler 100micrograms/actuation
6569	salmeterol with fluticasone cfc free inhaler 25micrograms + 125micrograms/actuation
549	serevent aerosol inhaler 25micrograms/actuation [glaxo]
5161	seretide 125 evohaler cfc free inhaler [a & h]
6325	symbicort turbohaler dry powder inhaler 200micrograms + 6micrograms/actuation [astrazenec]
556	combivent aerosol inhaler 20mcg + 100mcg [boeh ingl]
5864	salmeterol with fluticasone cfc free inhaler 25micrograms + 250micrograms/actuation
907	bricanyl turbohaler 500micrograms [astrazenec]
5172	seretide 250 evohaler cfc free inhaler [a & h]
1619	terbutaline dry powder inhaler 500micrograms
1741	salbutamol cfc free breath actuated inhaler 100micrograms/actuation
42830	ventolin evohaler cfc free inhaler 100micrograms/inhalation [glaxo]
465	salmeterol aerosol inhaler 25micrograms/actuation
898	ventolin evohaler 100micrograms/inhalation [glaxo]
31	ventolin aerosol inhaler 100micrograms/inhalation [glaxo]
8	salbutamol aerosol inhaler 100micrograms/inhalation
17	salbutamol cfc free inhaler 100micrograms/inhalation
25020	ipratropium bromide (forte)

8806	phyllocontin continus forte tablets 350mg [napppharm]
15284	slo-phyllin capsules 125mg [merck ser]
7733	theophylline modified release tablet 250mg
2609	franol tablets [sanofi s]
10331	nuelin liquid 60mg/5ml [3m]
1097	slo-phyllin capsules 60mg [lipha]
7732	theophylline modified release tablet 300mg
3388	theophylline modified release tablet 175mg
863	slo-phyllin capsules 125mg [lipha]
17002	aminophylline hydrate modified release tablet 225mg
6315	slo-phyllin capsules 250mg [merck ser]
2147	theophylline modified release capsules 250mg
1834	theophylline modified release tablet 400mg
1833	theophylline modified release tablet 200mg
5261	nuelin sa-250 tablets [meda]
2757	slo-phyllin capsules 250mg [lipha]
5941	uniphyllin continus prolonged release tablet 300mg [napppharm]
2995	nuelin sa tablets 175mg [meda]
5453	uniphyllin continus prolonged release tablet 400mg [napppharm]
1423	uniphyllin continus prolonged release tablet 200mg [napppharm]
555	aminophylline modified release tablet 225mg
590	phyllocontin continus tablets 225mg [napppharm]
25087	betamethasone /clioquinol
20763	becloforte
20825	spacehaler bdp spacehaler 250micrograms/actuation [celltech]
27915	fluticasone prop disk refill
24660	betamethasone valerate
41269	beclometasone cyclocaps capsules (for inhalation) 400micrograms [teva]
24205	betamethasone /neomycin
24219	becotide rotacaps
27083	betamethasone valerate .1 mg tab
27583	pulmicort
29322	betamethasone loz
28311	betamethasone /salicylic acid
26665	pulmicort complete
41412	beclometasone aerosol inhaler 400micrograms/actuation
22827	betamethasone .1 mg pel
30805	betamethasone valerate pel
21465	betamethasone .1 mg tab
34428	beclometasone aerosol inhaler 50micrograms/actuation [neolab]
27970	betamethasone sod phos 0.1%/neomycin 0.5
28761	spacehaler bdp spacehaler 50micrograms/actuation [celltech]
46157	beclometasone cyclocaps capsules (for inhalation) 200micrograms [teva]
34794	beclometasone aerosol inhaler 200micrograms/actuation [hillcross]
22180	betamethasone 0.1%/neomycin 0.5% een dro
19736	becotide susp for nebulisation
24898	spacehaler bdp spacehaler 100micrograms/actuation [celltech]
27525	becotide 50
34859	beclometasone aerosol inhaler 250micrograms/actuation [neolab]
20707	becotide 100
26414	betamethasone benzoate % cre
23675	pulmicort l.s. refil
32874	beclometasone aerosol inhaler 50micrograms/actuation [actavis]

Asthma therapy

Product Code	Product Name
20750	betamethasone sodium phosphate eye
7643	betamethasone dipropionate .1 % oin
36021	fluticasone inhalation powder blisters with device 50micrograms
33849	beclometasone aerosol inhaler 100micrograms/actuation [neolab]
18394	bdp spacehaler 50micrograms/actuation [celltech]
22160	betamethasone sod.phos. ear/eye/nose dro
34315	beclometasone aerosol inhaler 250micrograms/actuation [actavis]
19389	asmabec spacehaler 50micrograms/actuation [celltech]
37447	fluticasone inhalation powder blisters (refill) 50micrograms
34739	beclometasone aerosol inhaler 50micrograms/actuation [aps]
35986	flixotide diskhaler (refill) inhalation powder 50micrograms [a & h]
8232	betamethasone valerate /lignocaine hyd./ .05 % oin
7706	betamethasone 1 % oin
30238	beclometasone breath actuated inhaler 50micrograms/actuation [aps]
10321	budesonide capsules (for inhalation) 400micrograms
35392	flixotide diskhaler inhalation powder 500 micrograms [a & h]
36290	flixotide diskhaler inhalation powder 50micrograms [a & h]
18537	budesonide capsules (for inhalation) 200micrograms
2720	betamethasone /clioquinol oin
20812	pulmicort refill
33258	beclometasone aerosol inhaler 250micrograms/actuation [hillcross]
39200	aerobec forte autohaler 250micrograms/actuation [meda]
35374	flixotide diskhaler (refill) inhalation powder 500 micrograms [a & h]
35700	fluticasone inhalation powder blisters with device 500 micrograms
8251	pulmicort refil 50 mg inh
35225	flixotide diskhaler inhalation powder 100micrograms [a & h]
3860	betamethasone drops eye
35580	beclometasone inhalation powder blisters with device 100micrograms
4803	beclazone aerosol inhaler 250micrograms/actuation [actavis]
8829	betamethasone .05 % lot
16054	budesonide refillable breath actuated dry powder inhaler 200micrograms/actuation
7724	betamethasone valerate aerosol inhaler 100micrograms/actuation
14590	asmabec spacehaler 250micrograms/actuation [celltech]
28073	beclometasone breath actuated inhaler 250micrograms/actuation [aps]
3188	pulmicort complete 50 mcg inh
35638	fluticasone inhalation powder blisters with device 100micrograms
7964	beclometasone nebuliser suspension 50micrograms/ml
34919	beclometasone aerosol inhaler 50micrograms/actuation [hillcross]
36090	flixotide diskhaler (refill) inhalation powder 100micrograms [a & h]
35602	budesonide dry powder inhalation cartridge (refill) 200micrograms
35107	beclometasone inhalation powder blisters with device 400micrograms
9477	asmabec spacehaler 100micrograms/actuation [celltech]
35106	becodisks diskhaler inhalation powder 100micrograms [a & h]
36462	fluticasone inhalation powder blisters (refill) 500 micrograms
19031	bdp spacehaler 100micrograms/actuation [celltech]
35772	fluticasone inhalation powder blisters (refill) 100micrograms
14700	budesonide aerosol inhaler 400micrograms/actuation
26063	beclometasone aerosol inhaler 100micrograms/actuation [aps]
11198	beclometasone vortex metered dose inhaler 50micrograms/actuation
35461	flixotide diskhaler inhalation powder 250micrograms [a & h]
9599	beclazone aerosol inhaler 50micrograms/actuation [actavis]
35510	budesonide dry powder inhalation cartridge with device 200micrograms
3442	pulmicort complete 200 mcg inh
36401	fluticasone inhalation powder blisters with device 250micrograms
28640	beclometasone aerosol inhaler 100micrograms/actuation [actavis]
14524	bdp spacehaler 250micrograms/actuation [celltech]
35611	flixotide diskhaler (refill) inhalation powder 250micrograms [a & h]
35118	becodisks diskhaler inhalation powder 400micrograms [a & h]
35652	beclometasone inhalation powder blisters (refill) 100micrograms
19401	beclometasone inhaler with compact spacer 250micrograms/actuation
35293	beclometasone inhalation powder blisters with device 200micrograms

Asthma therapy

Product Code	Product Name
30649	easyhaler budesonide dry powder inhaler 400micrograms/actuation [orion]
35430	becodisks diskhaler inhalation powder 200micrograms [a & h]
35408	becodisks inhalation powder (refill) 100micrograms [a & h]
35288	beclometasone inhalation powder blisters (refill) 400micrograms
35905	fluticasone inhalation powder blisters (refill) 250micrograms
23741	novolizer budesonide breath actuated dry powder inhaler 200micrograms/actuation [meda]
43074	flixotide accuhaler dry powder inhaler 500micrograms/inhalation [a & h]
11497	beclometasone dry powder inhaler 400micrograms/actuation
31774	beclometasone aerosol inhaler 50micrograms/actuation [gen (uk)]
9571	beclometasone vortex metered dose inhaler 250micrograms/actuation
13815	beclazone aerosol inhaler 100micrograms/actuation [actavis]
35299	becodisks inhalation powder (refill) 400micrograms [a & h]
25204	beclometasone aerosol inhaler 100micrograms/actuation [hillcross]
35631	budelin novolizer inhalation powder with device 200micrograms [meda]
8433	budesonide aerosol inhaler 100micrograms/actuation
35724	budelin novolizer inhalation powder (refill) 200micrograms [meda]
42985	flixotide accuhaler dry powder inhaler 50micrograms/inhalation [a & h]
27679	beclometasone breath actuated inhaler 100micrograms/actuation [aps]
15706	beclometasone vortex metered dose inhaler 100micrograms/actuation
2124	pulmicort refil 200 mcg inh
21224	alvesco cfc free inhaler 80micrograms/actuation [nycomed]
27188	easyhaler budesonide dry powder inhaler 200micrograms/actuation [orion]
39099	pulmicort cfc free inhaler 100micrograms [astrazenec]
35071	becodisks inhalation powder (refill) 200micrograms [a & h]
11478	fluticasone unit dose nebulising suspension 2mg/2ml
29325	beclometasone aerosol inhaler 250micrograms/actuation [gen (uk)]
39102	budesonide cfc free inhaler 100micrograms
17590	asmanex twisthaler dry powder inhaler 400micrograms/actuation [m s d]
14736	pulvinal beclometasone dipropionate dry powder inhaler 400micrograms/actuation [chiesi]
40057	pulmicort cfc free inhaler 200micrograms [astrazenec]
8450	flixotide diskhaler-community pack 50 mcg
42994	flixotide accuhaler dry powder inhaler 250micrograms/inhalation [a & h]
35113	beclometasone inhalation powder blisters (refill) 200micrograms
16433	asmanex twisthaler dry powder inhaler 200micrograms/actuation [m s d]
16305	flixotide nebules unit dose nebulising suspension 2mg/2ml [a & h]
2892	becloforte disks (refill pack) 400micrograms/actuation [a & h]
19563	becotide for nebuliser
17465	fluticasone unit dose nebulising suspension 500micrograms/2ml
5992	beclometasone dry powder inhaler 50micrograms/actuation
6839	alvesco cfc free inhaler 160micrograms/actuation [nycomed]
3363	becloforte diskhaler 400micrograms/actuation [a & h]
5551	flixotide nebules unit dose nebulising suspension 500micrograms/2ml [a & h]
17670	easyhaler budesonide dry powder inhaler 100micrograms/actuation [orion]
3065	bextasol aerosol inhaler [a & h]
42928	flixotide accuhaler dry powder inhaler 100micrograms/inhalation [a & h]
16018	mometasone furoate dry powder inhaler 200micrograms/actuation
3570	budesonide refill canister 200micrograms/actuation
3743	filair aerosol inhaler 50micrograms/actuation [meda]
30210	beclometasone aerosol inhaler 250micrograms/actuation [aps]
7356	ciclesonide cfc free inhaler 80micrograms/actuation
9356	becotide rotahaler insufflator [a & h]
9577	asmabec clickhaler dry powder inhaler 50micrograms [focus]
39879	budesonide cfc free inhaler 200micrograms
10254	mometasone furoate dry powder inhaler 400micrograms/actuation
14757	pulvinal beclometasone dipropionate dry powder inhaler 100micrograms/actuation [chiesi]
3988	flixotide diskhaler-community pack 100 mcg
947	budesonide refill canister 50micrograms/actuation
7602	fluticasone disc 50micrograms
3119	becloforte integra inhaler with compact spacer 250micrograms/actuation [glaxo]

Asthma therapy

Product Code	Product Name
21482	beclometasone aerosol inhaler 100micrograms/actuation [gen (uk)]
10102	ciclesonide cfc free inhaler 160micrograms/actuation
2159	aerobec autohaler 50micrograms/actuation [meda]
8111	becloforte vm pack 250micrograms/actuation [a & h]
5804	beclometasone dry powder inhaler 250micrograms/actuation
13037	pulvinal beclometasone dipropionate dry powder inhaler 200micrograms/actuation [chiesi]
21005	beclometasone cfc free inhaler 250micrograms/actuation
8635	flixotide disc 50micrograms [a & h]
17654	easyhaler beclometasone dry powder inhaler 200micrograms/actuation [orion]
5521	beclometasone dry powder inhaler 200micrograms/actuation
1727	becotide easi-breathe breath actuated inhaler 50micrograms/actuation [a & h]
11732	beclometasone extrafine particle cfc free breath actuated inhaler 50micrograms/actuation
4545	pulmicort ls refill canister 50micrograms [astrazenec]
3753	flixotide diskhaler-community pack 250 mcg
16584	beclometasone cfc free inhaler 50micrograms/actuation
14321	beclometasone cfc free inhaler 200micrograms/actuation
3993	filair forte aerosol inhaler 250micrograms/actuation [meda]
1725	beclazone easi-breathe breath actuated inhaler 50micrograms/actuation [ivax]
4801	budesonide nebuliser suspension 0.5mg/2ml
7891	fluticasone disc 500micrograms
9921	beclometasone extrafine particle cfc free breath actuated inhaler 100micrograms/actuation
1426	flixotide disc 500micrograms [a & h]
4131	fluticasone disc 100micrograms
14567	asmabec clickhaler dry powder inhaler 250micrograms [focus]
4759	beclometasone capsules (for inhalation) 100micrograms
4365	beclometasone disc 100micrograms
3289	flixotide aerosol inhaler 25micrograms/actuation [a & h]
4499	aerobec forte autohaler 250micrograms/actuation [meda]
3989	flixotide disc 100micrograms [a & h]
1269	becotide nebuliser suspension 50micrograms/ml [a & h]
5522	beclometasone dry powder inhaler 100micrograms/actuation
2723	fluticasone aerosol inhaler 25micrograms/actuation
1885	beclazone aerosol inhaler 200micrograms/actuation [ivax]
4942	budesonide nebuliser suspension 1mg/2ml
3927	filair aerosol inhaler 100micrograms/actuation [meda]
5580	flixotide accuhaler 50micrograms/inhalation [a & h]
1518	flixotide aerosol inhaler 50micrograms/actuation [a & h]
4601	asmabec clickhaler dry powder inhaler 100micrograms [focus]
7653	beclometasone capsules (for inhalation) 400micrograms
4688	fluticasone aerosol inhaler 50micrograms/actuation
9164	fluticasone dry powder inhaler 50micrograms/inhalation
14294	qvar easi-breathe cfc free breath actuated inhaler 50micrograms/actuation [ivax]
2160	beclometasone breath actuated inhaler 50micrograms/actuation
18848	qvar easi-breathe cfc free breath actuated inhaler 100micrograms/actuation [ivax]
5309	flixotide evohaler cfc free inhaler 50micrograms/actuation [a & h]
2440	flixotide accuhaler 500micrograms/inhalation [a & h]
9233	beclometasone capsules (for inhalation) 200micrograms
7638	fluticasone disc 250micrograms
1552	becloforte easi-breathe breath actuated inhaler 250micrograms/actuation [a & h]
1959	pulmicort respules nebuliser suspension 0.5mg/2ml [astrazenec]
2992	beclazone aerosol inhaler 50micrograms/actuation [ivax]
5718	flixotide evohaler cfc free inhaler 125micrograms/actuation [a & h]
2125	pulmicort refill canister 200micrograms [astrazenec]
2282	fluticasone dry powder inhaler 500micrograms/inhalation
959	budesonide aerosol inhaler 50micrograms/actuation
2148	beclometasone disc 400micrograms
15326	beclometasone cfc free inhaler 100micrograms/actuation
10090	beclometasone extrafine particle cfc free inhaler 50micrograms/actuation
1676	flixotide aerosol inhaler 125micrograms/actuation [a & h]

Asthma therapy

Product Code	Product Name
1680	pulmicort ls aerosol inhaler 50micrograms [astrazenec]
1424	flixotide disc 250micrograms [a & h]
2893	beclometasone disc 200micrograms
4926	flixotide accuhaler 100micrograms/inhalation [a & h]
4132	fluticasone aerosol inhaler 125micrograms/actuation
1243	beclazone easi-breathe breath actuated inhaler 250micrograms/actuation [ivax]
3220	qvar autohaler cfc free breath actuated inhaler 50micrograms/actuation [ivax]
3150	beclometasone extrafine particle cfc free inhaler 100micrograms/actuation
1861	aerobec autohaler 100micrograms/actuation [meda]
1956	pulmicort respules nebuliser suspension 1mg/2ml [astrazenec]
5885	fluticasone dry powder inhaler 100micrograms/inhalation
911	flixotide accuhaler 250micrograms/inhalation [a & h]
7948	fluticasone dry powder inhaler 250micrograms/inhalation
5683	flixotide evohaler cfc free inhaler 250micrograms/actuation [a & h]
3947	becotide rotacaps 100micrograms [a & h]
896	becotide easi-breathe breath actuated inhaler 100micrograms/actuation [a & h]
2229	becodisks disc 100micrograms [a & h]
16148	clenil modulite cfc free inhaler 250micrograms/actuation [chiesi]
3437	becotide rotahaler type 4 insufflator [a & h]
5223	fluticasone cfc free inhaler 50micrograms/actuation
3075	becotide rotacaps 400micrograms [a & h]
7788	budesonide dry powder inhaler 100micrograms/actuation
2600	beclometasone breath actuated inhaler 250micrograms/actuation
4413	qvar autohaler cfc free breath actuated inhaler 100micrograms/actuation [ivax]
5975	fluticasone cfc free inhaler 125micrograms/actuation
1412	flixotide aerosol inhaler 250micrograms/actuation [a & h]
895	beclazone easi-breathe breath actuated inhaler 100micrograms/actuation [ivax]
1551	beclazone aerosol inhaler 250micrograms/actuation [ivax]
960	pulmicort turbohaler dry powder inhaler 100micrograms/actuation [astrazenec]
2951	fluticasone aerosol inhaler 250micrograms/actuation
883	becodisks disc 200micrograms [a & h]
1951	becodisks disc 400micrograms [a & h]
16151	clenil modulite cfc free inhaler 200micrograms/actuation [chiesi]
909	budesonide aerosol inhaler 200micrograms/actuation
1642	budesonide dry powder inhaler 400micrograms/actuation
5822	fluticasone cfc free inhaler 250micrograms/actuation
1100	beclazone aerosol inhaler 100micrograms/actuation [ivax]
1537	becotide rotacaps 200micrograms [a & h]
16158	clenil modulite cfc free inhaler 50micrograms/actuation [chiesi]
454	pulmicort aerosol inhaler 200micrograms [astrazenec]
908	pulmicort turbohaler dry powder inhaler 400micrograms/actuation [astrazenec]
1258	becotide 200 aerosol inhaler 200micrograms/actuation [a & h]
1406	becotide 50 aerosol inhaler 50micrograms/actuation [a & h]
2092	budesonide dry powder inhaler 200micrograms/actuation
1734	beclometasone breath actuated inhaler 100micrograms/actuation
956	pulmicort turbohaler dry powder inhaler 200micrograms/actuation [astrazenec]
3546	qvar cfc free inhaler 50micrograms/actuation [ivax]
3018	beclometasone aerosol inhaler 50micrograms/actuation
2335	qvar cfc free inhaler 100micrograms/actuation [ivax]
1236	becloforte aerosol inhaler 250micrograms/actuation [a & h]
13290	clenil modulite cfc free inhaler 100micrograms/actuation [chiesi]
1259	beclometasone aerosol inhaler 200micrograms/actuation
1242	beclometasone aerosol inhaler 250micrograms/actuation
99	becotide 100 aerosol inhaler 100micrograms/actuation [a & h]
38	beclometasone aerosol inhaler 100micrograms/actuation
28977	intal spincaps
24387	intal
12633	tilarin nasal spray 1% [rhone]
14448	nedocromil sodium nasal spray 1%
19643	intal nebuliser solution (2ml)
3585	steri-neb cromogen nebuliser solution 10mg/ml [ivax]
37615	sodium cromoglicate aerosol inhaler 1mg/inhalation

Asthma therapy

Product Code	Product Name
15765	sodium cromoglicate inhaler and spacer 5mg/inhalation
4647	intal syncroner 5mg/inhalation [aventis]
14603	sodium cromoglicate inhaler and spacer 5mg/actuation
38501	intal cfc free inhaler 5mg [sanofi/ave]
10361	intal syncroner 5 mg inh
7580	intal whistle
25119	tilade cfc free inhaler 2mg/inhalation [sanofi/ave]
38471	sodium cromoglicate cfc free inhaler 5mg
8498	sodium cromoglicate nebuliser solution 10mg/ml
19597	intal
2158	sodium cromoglicate breath actuated inhaler 5mg/inhalation
13256	nedocromil sodium cfc free inhaler 2mg/inhalation
1728	cromogen easi-breathe breath actuated inhaler 5mg/inhalation [ivax]
10597	tilade mint syncroner 2mg/inhalation [sanofi/ave]
4100	intal autohaler 5mg/inhalation [aventis]
7972	intal fisonair aerosol inhaler 5mg/inhalation [aventis]
8608	nedocromil sodium aerosol inhaler 2mg/inhalation
1629	intal nebuliser solution 10mg/ml [aventis]
2911	sodium cromoglicate capsules (for inhalation) 20mg
3688	tilade mint inhaler 2mg/inhalation [sanofi/ave]
8215	tilade aerosol inhaler 2mg/inhalation [sanofi/ave]
1422	cromogen aerosol inhaler 5mg/inhalation [ivax]
2260	intal spinhaler insufflator [aventis]
964	sodium cromoglicate aerosol inhaler 5mg/inhalation
1683	intal spincaps inhalation powder capsules [aventis]
314	intal aerosol inhaler [aventis]
17701	zafirlukast
17894	accolate
20817	tilade aerosol
14200	singulair paediatric granules 4mg/sachet [m s d]
1973	accolate tablets 20mg [astrazenec]
14162	singulair paediatric chewable tablet 4mg [m s d]
