ABSTRACT

Interrupted time series analysis differs from most other intervention study designs in that it involves a before-after comparison within a single population rather than a comparison with a control group. This has the advantage that selection bias and confounding due to between-group differences are limited. However, the basic interrupted time series design cannot exclude confounding due to co-interventions or other events occurring around the time of the intervention. One approach to minimise potential confounding from such simultaneous events is to add a control series so that there is both a before-after comparison and an intervention-control group comparison. A range of different types of controls can be used with interrupted time series designs, each of which have associated strengths and limitations. Researchers undertaking controlled interrupted time series studies should carefully consider a priori what confounding events may exist and whether different controls can exclude these or if they could introduce new sources of bias to the study. A prudent approach to the design, analysis and interpretation of controlled interrupted time series studies is required to ensure that valid information on the effectiveness of health interventions can be ascertained.
KEY MESSAGES

- History bias due to other interventions or events occurring around the time of the intervention is the primary threat to the validity of interrupted time series studies.

- A wide range of different controls can be used in order to limit history bias and improve the validity of an ITS study.

- Controls should be selected by considering, a priori, the possible sources of history bias and examining for differential changes in covariates between the study series and the control series throughout the study period.

- Researchers should take care in interpreting the results of controlled interrupted time series studies, in particular when the results differ from those of simple (uncontrolled) analysis.
INTRODUCTION
Evaluation of public health interventions normally relies on comparing the outcome of interest in a population exposed to an intervention to that in an external control group not subject to the same intervention.(1) Interrupted time series (ITS) is an increasingly popular design that adopts a different approach whereby comparisons are instead made across time within a single population.(2) This design is generally applied to natural experiments with an intervention introduced at a known point in time. By collecting data at regular intervals over time, a pre-post comparison can be made while accounting for underlying trends in the outcome.(2) Because the evaluation is based on observing a single population over time, the ITS design is free from problems due to between-group differences, such as selection bias or unmeasured confounders. Furthermore, by modelling the underlying trend, ITS also controls for within-group characteristics that tend to change only slowly over time, secular changes, random fluctuations from one time point to the next and regression to the mean.(3, 4) Nevertheless, ITS studies cannot exclude time-varying confounders which do not form part of the underlying trend, for example other interventions or events occurring around the time of the intervention that may also affect the outcome.(5)

One approach that limits the threat of these other confounding events is to include a control series, a design known as a controlled (or comparative) interrupted time series (CITS) analysis. A lack of effect in a well-chosen control can provide stronger evidence to support a causal relationship between the intervention and outcome. Conversely, the presence of an effect in the control series indicates that the change may be attributable to different factors. Indeed, a number of recent within study comparisons have provided empirical evidence of the validity of the CITS design by demonstrating comparable results to RCT benchmarks.(6-9) Nevertheless, while the basic ITS design has been described in detail elsewhere and reference is made to the inclusion of a control as a method of improving the validity of the design,(2, 10) there is little guidance available on the what a control series can and cannot solve and how to select an appropriate control in CITS studies. The purpose of this
paper is to evaluate the use of controls in ITS studies and provide a framework for their selection, analytical approaches and the interpretation of results. We then provide an illustration of the application of this framework using an example from a recent study where alternative types of controls can be selected and compared.

EVALUATIVE STUDY DESIGNS
In order to know whether an intervention has caused an effect, a comparison needs to be made between the observed change in the outcome and the counterfactual, that is, what would have happened if the intervention had not taken place. Of course, it is not possible to observe the intervention both being implemented and not being implemented in the same individuals in the same population at the same time, therefore the true counterfactual is never known. Evaluation design is therefore centred on creating the best approximation of the true counterfactual and then comparing what happened in the intervention group to the approximated counterfactual. (3) There are two main approaches to approximating the counterfactual: controlled designs and before-and-after designs. (3)

**Controlled designs:**
Controlled designs normally compare the same outcome in the intervention group and an external control. Randomised controlled trials, cross sectional studies as well as other designs less commonly used for intervention evaluations (such as cohort and case control studies) all make comparisons between a intervention group and a control. The advantage of this approach is that both intervention and control groups are compared at the same point in time so other time sensitive factors that would affect both populations (such as other interventions or events that might impact on the outcome of interest) can be excluded. Nevertheless, selection bias and differences between the intervention and control population may mean that observed effects could be due to other confounding factors (which may be unknown or difficult to measure) rather than the intervention. (1) Randomisation addresses this limitation in experimental studies, however this is often not desirable, feasible or practical in
studies evaluating public health interventions. (1, 11, 12) Other approaches, such as adjusting for multiple variables in regression models or propensity score matching can account for known characteristics that differ between the two groups, but cannot control for unmeasured confounders. (1, 12, 13)

**Before-and-after designs:**
Before-after designs involve making a comparison between a period of time after the intervention has occurred and a period of time before the intervention within a single population. Here, the pre-intervention period effectively acts as the control. Simple pre-post designs make before-after comparisons by estimating the change from a single pre-intervention time point to a single post-intervention time point. However, these have poor internal validity as they cannot exclude underlying trends as a cause for any change. Conversely, interrupted time series use multiple pre-intervention and post-intervention observations, thereby allowing the underlying trend to be accounted for. These have the advantage that confounding is rarely a problem as population characteristics tend to only change gradually over time. (3, 14) Nevertheless, such before-after comparisons cannot exclude other events or co-interventions occurring around the same time as the intervention under investigation as the cause of any detected change in the outcome. This phenomenon is known as history bias in Campell and Stanley’s classical list of threats to internal validity. (5)

**CONTROLLED INTERRUPTED TIME SERIES**
Controlled (or comparative) interrupted time series (CITS) involves adding a control series, which was not exposed to the intervention, to the basic ITS design (Figure 1). (9) This results in the definition of a more complex counterfactual based on both a before-and-after comparison and an intervention-control comparison. The primary benefit of this approach is that it can help to control for history bias due to time-varying confounders, in particular co-interventions and other events concurrent to the intervention. (3) In a CITS, if an effect is detected in the intervention group but not in a well-chosen control (Figure 1a) this suggests that the effect is more likely to be due to the intervention; conversely
if an effect is detected in both the intervention and control series (Figure 1b), this suggests that it is due to some confounding event.

![Figure 1: Controlled interrupted time series](image)

Red line = intervention series, green line = control series. (a) Here there is an effect in the intervention series (step and slope decrease) but no effect in the control series which increases confidence that the effect is due to the intervention. (b) Here there is a step and slope decrease in both the intervention and control series suggesting the change is due to some other event or co-intervention that affected both groups.

CITS is related to other study designs applied in evaluation analyses. For instance, the controlled before and after design (CBA) also involves a before-and-after and intervention-control comparison. Nevertheless, the CBA design involves a comparison of a single pre and a single post intervention, or a comparison of pre and post-intervention means. While both CITS and CBA designs involve a difference in difference calculation, CBA designs do not take into account baseline trends and therefore use the control group alone in order to approximate the counterfactual.\(^{(3, 15)}\)

An extension of the CITS design is the multiple baseline design. This is similar to a stepped wedge cluster randomised trial but typically does not involve randomisation. Here, following a baseline period, the intervention is first introduced in one group while one or more other groups act as a control.\(^{(16, 17)}\) The intervention is subsequently introduced in other groups at different times, with a different subset acting either as intervention or control groups at each time. In this design, the observation of an effect of similar strength and magnitude following the intervention in multiple
different groups at multiple sequential time points, can provide strong evidence that the observed effect is due to the intervention rather than other potential confounding events.\(^{(16, 17)}\)

**SELECTING A CONTROL**
With studies that rely on the control as the sole means of approximating the counterfactual (including RCTs, cross-sectional studies and CBA studies) the central prerequisite when selecting a control is that it is as similar as possible to the intervention group. The ideal control is the same in terms of all variables other than exposure to the intervention.\(^{(1, 3)}\) RCTs accomplish this through randomisation. Where randomisation is not possible a range of methods have been developed to achieve covariate balance in cross-sectional and CBA designs including multivariable regression, propensity score matching and synthetic controls.\(^{(18-20)}\) Nevertheless, none of these methods can account for systematic differences in unknown variables.\(^{(18, 21)}\)

As described above, ITS studies use the pre-intervention trend to predict the counterfactual. The purpose of the control in this case is to exclude time varying confounders, in particular co-interventions or other events occurring around the time of the intervention, as these are generally unpredictable based on modelling pre-intervention trends.\(^{(2, 3)}\) It follows that the key attribute of a control series for a CITS study should be its ability to control for known co-interventions or external events that may affect the outcome. Therefore, the control series should be exposed to any such co-interventions or events that might also affect the intervention series, however, it should not be exposed to other interventions or events that could impact on the control series alone (and not the intervention series). The latter could result in artifactual effects being detected in the CITS which are in fact due to independent changes in the control series. Several different types of control series have been used for CITS analyses; we have broadly classified some of the most commonly used controls as follows: location based control groups, characteristic based control groups, behaviour based control

7
groups, historical cohort controls, control outcomes and control time periods. Table 1 describes these six types of controls, each of which may plausibly control for different sources of confounding events.

Researchers should also consider whether the intervention under study could have an indirect effect on the control series, for example there may be a contamination effect in location based or characteristic based control groups, or a substitution effect with control outcomes. A contamination effect occurs when the effects of the intervention spreads beyond the target population, for example with behaviour change interventions, whereby members of the control population learn about the new behaviour and adopt it themselves. An example of a substitution effect would be an evaluation of the effect of an intervention aimed at reducing the prescription of a certain drug; in this scenario, prescriptions of a similar drug not targeted by the intervention may be considered as a control intervention, however, doctors may substitute the targeted drug with the similar drug so that it is indirectly affected by the intervention. Control series that could be indirectly affected by the intervention should be excluded.

Finally, while covariate balance between the intervention and control series in ITS is not required to predict the counterfactual, and is therefore not the fundamental prerequisite that it is in other controlled designs, it remains important for two reasons: firstly, certain subgroups may be more susceptible to either an intervention or a confounding event than others. If such a subgroup is more concentrated in the intervention group than the control, one would expect a greater effect in the intervention group simply due to the population distribution. Secondly, if certain characteristics are associated with the outcome and these characteristics change differentially over time in the intervention and control groups, the trend in the outcome may change in one group but not the other simply due to differential changes in the populations under investigation. For example, there is evidence that rates of cycle head injuries are lower in females than in males. In the cycle helmet
legislation study by Dennis et al described in Table 1, if the intervention population had a higher proportion of females at baseline than the control population this would not necessarily be a problem. Nevertheless, if the proportion of females increased more rapidly in the intervention group than in the control population following the intervention, this would be a source of confounding as there may be a decrease in head injuries in the intervention group simply due to the population change, rather than any effect of the intervention. Matching techniques, including propensity score matching can be used to ensure balance of known covariates at baseline which can help to limit the effects of differential susceptibility to the intervention by population subgroup. Furthermore, synthetic control approaches can be applied to ITS studies where multiple potential controls exist. This approach reweights a range of different control groups so that the weighted average of their baseline characteristics is as similar as possible to those of the study group (maximising covariate balance). Linden 2018 demonstrates an example of the use of synthetic controls in interrupted time series which produces strong covariate balance and no significant difference from the intervention group in terms of pre-intervention level and trend in the outcome. Nevertheless, whether matching or using synthetic controls, it is still important to check for covariate balance between the control and intervention group throughout the study period. If there are changes over time, variables associated with the outcome can be included in the interrupted time series regression model to adjust for confounding. However, none of these methods can control for unknown confounding and this should be recognised as a limitation of CITS studies in common with other non-randomised controlled designs.

<tr>
<th>Type of Control</th>
<th>Description</th>
<th>Examples</th>
<th>Strengths</th>
<th>Limitations</th>
</tr>
</thead>
<tbody>
<tr>
<td>Location based control</td>
<td>The control series is selected from another location similar to the study location but that did not receive the intervention. The type of location depends on the scale of the intervention, for large scale interventions this can be more complex.</td>
<td>Dennis et al (2013) evaluated the impact of the introduction of helmet legislation in a number of Canadian provinces on cycling related head injuries by comparing outcomes in Canadian provinces that had introduced helmet legislation with those that had not.</td>
<td>Help to control for confounding events that would affect both locations. For example, changes in weather, traffic conditions, etc.</td>
<td>Cannot exclude events that are unique to the intervention location. For example, in the study of helmet legislation, reductions in head injuries could be due to a protective effect.</td>
</tr>
<tr>
<td>Characteristic based control</td>
<td>Interventions are sometimes targeted according to certain characteristics, for example only males or only females, a certain age group, a specific ethnic minority group or patients with a certain diagnosis. Controls may be chosen from those groups that were not targeted.</td>
<td>Feigl et al (2015) investigated the impact of a national ban on smoking in high schools and selected a control based on age by comparing trends in smoking prevalence among those aged 12-18 years compared to those aged 19-24 years. (29) Kontopantelis et al (2015) examined the impact of a national primary care financial incentive scheme on trends in consultation rates among patients with severe mental illness compared to matched patient controls with no severe mental illness. (30) In cross sectional or similar designs, this type of control is not ideal as the characteristic that differentiates the two groups is a known confounder that cannot be controlled for, nevertheless in ITS studies, where the pre-intervention trend is the primary control, characteristic control groups can help to exclude concurrent events to the intervention that both groups would have been exposed to.</td>
<td>Interventions may have been targeted at the intervention group because of a detected deviation in the trend, for example in the smoking ban study, high schools may have been targeted because of recent increases in smoking among adolescents therefore trends could differ substantially from the control group. (29)</td>
<td></td>
</tr>
<tr>
<td>---</td>
<td>---</td>
<td>---</td>
<td>---</td>
<td></td>
</tr>
<tr>
<td>Behaviour based control</td>
<td>Sometimes the intervention does not affect all of those within the population to whom it is targeted, this tends to occur when the intervention targets a behaviour that some individuals never performed (either prior to the intervention starting or since). Those individuals who never performed the behaviour can therefore be used as a control group.</td>
<td>Ross-Degnan et al (1993) evaluated the impact of the national withdrawal of a non-steroidal anti-inflammatory drug (Zomepirac) on prescribing of other analgesics. They used physicians who never prescribed Zomepirac (and were thus unaffected by its withdrawal) as the control group. (23) Kiseley et al (2011) used a CITS to evaluate the impact of an increase in taxation of “alcopops” on alcohol related harm by comparing the effect in young people aged 15-29 to the effect in those aged 30-49. Alcopops tend to be favoured by Controls can be very similar to the intervention group other than in the specific behaviour targeted by the intervention.</td>
<td>It may be difficult to directly identify those who did not perform the behaviour, therefore, a proxy may have to be used – such as, age, in the alcopops study. This proxy may, however, introduce selection bias for example selecting based on age could bias the alcopops study because age could be independently associated with both the intervention (younger people may be lower earners and thus more affected by a tax increase) and the outcome (if rates of alcohol</td>
<td></td>
</tr>
<tr>
<td>Historical cohort control</td>
<td>Historical cohorts are commonly used in the evaluation of education interventions but have also been used for healthcare evaluations. This is possible where a cohort periodically progresses to another level (for example moving from one school year to the next) and is replaced by another cohort. The intervention cohort can then be compared to a previous or subsequent cohort.</td>
<td>Schneeweis et al (2004) evaluated the impact of a restriction of state funding of nebulised respiratory medication. The intervention time series used monthly observations of nebulised drug expenditure, primary care visits and admissions to emergency department for a year (6 months prior to the policy and 6 months after the policy). Control series were taken from the same population one year and two years before.</td>
<td>Historical cohorts help to rule out seasonal effects (such as stockpiling of drugs in the Schneeweis et al study) and events that occur on an annual basis. They would not control for events that are unique to the year in which the intervention was implemented.</td>
<td></td>
</tr>
<tr>
<td>Control outcome</td>
<td>Where no control group is possible, another option is to compare the effect on the primary outcome to that in a related ‘control outcome’ (or ‘non-equivalent dependant variable’) within the same group. Such an outcome should not be affected by the intervention, but would be affected by confounding events.</td>
<td>Walter et al (2011) conducted a study on the impact of helmet legislation on head injuries in Australia (similar to that by Dennis et al described above). Rather than other locations, they used limb injuries as a control outcome to exclude other effects on cycling. Lopez Bernal et al (2016) used accidental deaths as a control outcome in their ITS study of the impact of the financial crisis on suicides in Spain as both suicides and accidental deaths undergo similar judicial review and recording methods. This enabled them to control for other events that could have impacted on these processes.</td>
<td>Uses the same group as an intervention population therefore it is not sensitive to many of the between group differences that can affect other controls. Can often be used to control for potential confounders that would only affect the intervention group. For example by using limb injuries as a control outcome Walter et al were able to control for any changes in the number of cyclists where comparing to different states could not.</td>
<td></td>
</tr>
<tr>
<td>Control time period</td>
<td>It may be possible to use the primary outcome as its own control for interventions that are only active at certain times (certain times of day or days of the week). In this case the outcome during times Ross et al (1970) studied the impact of 1967 British Road Safety Act, which increased the use of breathalysers to reduce drink driving, on traffic casualties. They compared the effect on the weekend evenings when pubs are busiest</td>
<td>Uses the same group as the intervention group therefore it is not sensitive to many of the between group differences that can affect other controls.</td>
<td>Can only be used for short-term outcomes with rapid onset. The outcome must be recorded at a sufficiently high time resolution to allow identification of when the intervention is active.</td>
<td></td>
</tr>
</tbody>
</table>
in which the intervention is inactive act as the control.

and accidents are more likely to be due to drink driving to that at commuting hours when pubs are closed and accidents are less likely to be due to drink driving.(35)

and inactive. For example to the nearest hour if the intervention is only active at night time.(36)

ANALYSIS AND INTERPRETATION OF CITS STUDIES

There are a range of analyses that can be employed when undertaking CITS studies. These can broadly be divided into two: separate analysis of the intervention series and the control series; or a single model incorporating both series. Separate analysis is the simpler approach and may be suitable, particularly if there is no change in the control series. A single model can be developed by including indicator variables for the intervention or control series as interaction terms (web appendix 1) or by generating a new series of the ratio or difference between the intervention and control series at each time point.(6, 37) This approach provides a test of the differential effects of the intervention (level or slope change) across the groups. The benefit of this approach is that if there are trend changes in the control series which could be due to some confounding event, any additional effect of the intervention can still be calculated.

Even if a single model combining the intervention and control series is selected, we would recommend starting with a simple (uncontrolled) ITS of the intervention group. Both the uncontrolled ITS and the CITS should always be planned a priori and the results reported with equal prominence. If the result of the simple ITS mirrors that of the CITS this provides a greater degree of confidence that any association between intervention and effect is likely to be causal. Results should be interpreted more cautiously if either the simple ITS shows an effect but the CITS shows no effect (or a smaller effect) or if the CITS shows an effect but the simple ITS does not. If the simple ITS shows an effect but the CITS does not, then there may have been a change in both the intervention and the control series – this suggests possible history bias due to some simultaneous event or co-intervention.3 If the CITS shows
an effect but the simple ITS does not, the change may be due (at least in part) to a change in the control series, as a result of some other event that affected the control population but not the intervention group. This framework for analysing and interpreting CITS studies is summarised in Figure 2.

Analysis of CITS studies requires careful consideration of a number of statistical issues particular to time series data including overdispersion, autocorrelation and seasonality. Furthermore, where multiple controls or intervention groups are used, clustering effects need to be taken into consideration. These analytical issues are beyond the scope of this paper but have been described in more detail elsewhere.(2, 38-40)

It should be noted that the CITS model, outlined above and in web appendix 1, works best where the underlying trend is linear. Where non-linear trends exist, non-linear terms can be included within the time series model, nevertheless, the more complex the trend, the more difficult it becomes to differentiate intervention effects from underlying fluctuations in the trend.(41) Where complex pre-intervention trends exist, it may be preferable to use a generalised difference in difference approach. This has fewer restrictions on the shape of the time trend, however, this approach does assume that the treatment and control groups follow parallel trends. In either case, it is important that the assumption of linearity or parallel trends is checked.
SENSITIVITY ANALYSIS

Different ITS model assumptions can be checked using sensitivity analyses. Specific to CITS designs, different types of controls may control for different sources of bias or confounding events. Therefore, where possible researchers should undertake sensitivity analyses using different types of controls to control for those potential sources of bias that have been identified a priori. Similar to the primary model, sensitivity analyses should be clearly pre-specified to avoid the possibility of ‘data dredging’.
ILLUSTRATIVE EXAMPLE

Steinbach et al (2015) recently used a CITS design to evaluate the impact of a range of changes to streetlights in various regions of the UK on road traffic crashes and crime at night.\(^{36, 42}\) The purpose of the intervention was to save energy and costs. The intervention consisted of reductions in the brightness of streetlights, replacement of bulbs with lower energy consumption bulbs, reducing the hours during which streetlights were turned on at night (i.e. turning on later and turning off earlier) and reducing the ambient light threshold at which sensors would activate streetlights. The authors hypothesised that while the intervention may save costs, reduced street lighting may unintentionally increase road traffic crashes and crime at night. To illustrate the design and interpretation of CITS studies we used an extract of these data on minor roads in the Birmingham and Black Country region to analyse the impact of the intervention (introduced from 2010) on the number of casualties from road traffic crashes. Outcome data was taken from the STATS19 Road Accident dataset, a STATS19 report form is completed by police officers for all accidents involving human injury or death. This includes information on the location, date and time of the accident and the severity of the injury. Note that, for simplicity of this illustration, we make the assumption that the intervention was introduced simultaneously in 2010 throughout the region and that it would have a step change effect. A number of different controls can be considered for the analysis and we work through the process of selecting controls and analysing the CITS.

Data on road traffic crash casualties included variables on the region, the road type and the time of the road traffic crash. Therefore, three potential controls could be considered (1) another region as a location based control, (2) comparison of casualties from road traffic crashes on minor roads to those on major roads as a characteristic based control, (3) comparison of road traffic crash casualties at night to road traffic crash casualties during the day when street lights are not in use as a control time period.
Our first step in selecting a control is to identify potential confounding events or co-interventions that would affect the study outcome. In this study other changes to roads, such as changes to road layout or new road safety measures, were identified as a potential confounding event that could impact on road traffic crashes independently of the street lighting interventions. Another potential concern was instrumentation effects due to unidentified changes to data collection. Data quality reports suggest that “local circumstances (for example organisational changes, reviews of coding practice and local initiatives) may affect the data and trends over time”. Considering each of the controls in turn: the location based control would not be able to control for the identified confounding factors as road changes may have differed from one region to the next and data collection was separate in each region. The characteristic controls (different road types), would control for changes to data collection processes within a region but would not be able to control for road changes as these are likely to differ between minor and major roads. In this example, the control time period is the most appropriate as this uses the same roads and same data source and should therefore adequately control for all known potential confounders. No other interventions or events that would only affect day time road traffic crashes were identified and it was considered unlikely that the intervention would have any indirect effect on this control. Day time road traffic crashes were therefore selected as the control series.

The next step was to check characteristics of the control and intervention series at baseline and throughout the study period for covariate balance. We know that the data comes from the same roads therefore this will not be different between night and day. However, no data on the characteristics of the population of night time drivers compared to day time drivers were available. One might assume that there are fewer elderly drivers with visual impairments at night, however this is unlikely to change differentially between the intervention and control group over the study period independently of the intervention.
Figure 3 shows the results of the analysis. First, an uncontrolled ITS analysis (Figure 3a) was undertaken. This shows a significant decrease in road traffic crash casualties following the intervention, contrary to the hypothesised increase. Nevertheless, when a CITS analysis using daytime road traffic crash casualties is run (Figure 3b), the decrease is also present in the controls series and there is no evidence of any additional effect in the intervention series. This suggests that the effect is due to a change occurring at the same time as the intervention and biasing the previously estimated association.

To demonstrate the possible consequences of poor control selection, in figure 3c a location based control is used instead. We select the most closely matched region according to baseline characteristics (including number of roads in the region, population size, age distribution, sex distribution and level of unemployment). There is also no significant difference in baseline trends between the control and intervention group. In this case the results are very similar to the uncontrolled analysis, showing strong evidence of a decrease in road traffic crash casualties following the intervention. Nevertheless, this control group is clearly unable to account for changes to road layout or changes to data collection that are unique to the region, and could result in erroneous conclusions about the effect of the intervention. This highlights the potential pitfalls of selecting controls without first carefully considering potential confounding events or co-interventions specific to the study context, even when there is good covariate balance between the intervention and control group.

Where multiple possible confounding events exist, at may be best to use multiple different types of controls that can exclude different factors and can provide a more detailed picture of the intervention
effect. For example, it is possible that the reduction in streetlighting could result in a substitution effect whereby people with poor vision are less inclined to drive at night following the intervention due to poorer lighting and do more of their driving during the day. This could therefore actually result in a reduction in night time accidents. In order to examine this, one might consider comparing an analysis using the control time period and location based control.
Figure 3: The effect of the Birmingham and Black Country street lighting intervention on road traffic crash casualties

Red regression line is the intervention series (night time road traffic casualties on minor roads in Birmingham and the Black Country); blue regression line is the control series: (a) no control, (b) control time period: day time road traffic crash casualties on minor roads in Hertfordshire (c) location based control: night time road traffic crash casualties on major roads in West Yorkshire. The vertical red line is the intervention point. The incident rate ratio (IRR) is the step change in road traffic crash
casualties following the intervention compared to before the intervention, in figures (b) and (c) the IRR is the step change in
the intervention series over and above any step change in the control series.

CONCLUSION
In this paper we have highlighted how ITS studies differ from other evaluation designs by making
within group rather than between group comparisons. While this has the advantage of limiting
confounding by factors that change only slowly through time history bias can still threaten the validity
of ITS studies. A wide range of different controls can be used in order to limit history bias and improve
the validity of an ITS study. Nevertheless, it is important to systematically consider a priori the degree
of risk of history bias associated with any particular study, what control series are available and
whether these will adequately control for history bias. Finally, researchers should take care in
interpreting the results of CITS studies, in particular when the results of CITS analysis differ from those
of simple (uncontrolled) ITS analysis. If the results of the CITS and the ITS analysis are aligned, CITS
studies can provide strong evidence on the effectiveness of public health interventions and when
appropriate controls are selected the design ranks second only to randomised controlled designs in
terms of their capacity to control for bias.(14)
