13

14 **Abstract**

15

16 **Background**

17 Repeated culture reduces within-sample *Mycobacterium tuberculosis* genetic diversity due  
18 to selection of clones suited to growth in culture and/or random loss of lineages, but it is  
19 not known to what extent omitting the culture step altogether alters genetic diversity. We  
20 compared *M. tuberculosis* whole genome sequences generated from 39 paired clinical  
21 samples. In one sample DNA was extracted directly from sputum then enriched with  
22 custom-designed SureSelect (Agilent) oligonucleotide baits and in the other it was extracted  
23 from mycobacterial growth indicator tube culture.

24

25 **Results**

26 DNA directly sequenced from sputum showed significantly more within-sample diversity  
27 than that from mycobacterial growth incubator tube culture. This was demonstrated by  
28 more variants present as heterozygous alleles (HAs) where both a variant and wild type  
29 allele were present within a given sample ( $p < 0.001$ ) and greater within-sample Shannon  
30 diversity ( $p < 0.001$ ). Seven genes with high within-sample diversity have previously been  
31 identified as targets for positive selection, highlighting their potential role in adaptation to  
32 survival within the host and under drug pressure. Resistance associated variants present as  
33 HAs occurred in six patients, and in four cases may have provided a genotypic explanation  
34 for phenotypic resistance.

35

36 **Conclusions**

37 Culture-free *M. tuberculosis* whole genome sequencing detects more within-sample

38 diversity and may allow detection of mycobacteria that are not actively replicating.

## 42 Background

43

44 International efforts to reduce tuberculosis (TB) infections and mortality over the last two  
45 decades have only been partially successful. In 2017, 10 million people developed TB and it  
46 has overtaken HIV as the infectious disease responsible for the most deaths worldwide(1,  
47 2). Drug resistance is a major concern with a steady rise in the number of reported cases  
48 globally and rapid increases in some areas(1). Patients with *Mycobacterium tuberculosis*  
49 resistant to the first line drugs rifampicin and isoniazid are classed as having multidrug-  
50 resistant (MDR) TB and usually treated with a standardised second-line drug regimen for at  
51 least nine months, which is also used for rifampicin mono-resistance(3, 4). With the  
52 emergence of resistance to fluoroquinolones and aminoglycosides (extensively drug-  
53 resistant [XDR] TB) there is an increasing need for individualised therapy based on drug  
54 susceptibility testing (DST). Individualised therapy ensures patients are treated with  
55 sufficient active drugs which can prevent selection of additional resistance, improve  
56 treatment outcomes and reduce duration of infectiousness(5-8).

57

58 Traditionally, phenotypic culture-based DST was used to identify drug resistance but this is  
59 being replaced by rapid genetic tests that detect specific drug resistance conferring  
60 mutations. Next generation whole genome sequencing (WGS) of *M. tuberculosis* is being  
61 increasingly used in research and clinical settings to comprehensively identify all drug  
62 resistance associated mutations(9). *M. tuberculosis* has a conserved genome with little  
63 genetic diversity between strains(10), but more detailed analysis of individual patient  
64 samples with WGS has identified genetically separate bacterial subpopulations in sequential  
65 sputum samples(11-15) and across different anatomical sites(16). This within-patient

66 diversity can occur as a result of mixed infection with genetically distinct strains or within-  
67 host evolution of a single infecting strain(17).

68

69 Bacterial subpopulations can be detected in clinical samples after sequencing reads are  
70 mapped to a reference genome where multiple base calls are detected at a single genomic  
71 site. These heterozygous alleles (HAs) at sites associated with drug resistance (resistance  
72 associated variants, RAVs) may reflect heteroresistance, where a fraction of the total  
73 bacterial population is drug susceptible while the remainder is resistant(18). Identification  
74 of genetic diversity within clinical samples is important as it may improve detection of RAVs  
75 over currently available genetic tests and consensus-level WGS(18). Identifying RAVs could  
76 improve individualised therapy, prevent acquired resistance(12), and give insight into  
77 bacterial adaptation to the host.

78

79 *M. tuberculosis* WGS is usually performed on cultured isolates to obtain sufficient purified  
80 mycobacterial DNA. However, the culture process can change the population structure from  
81 that of the original sample due to genetic drift (random loss of lineages) and/or the  
82 selection of subpopulations more suited to growth in culture(19-21), and repeated  
83 subculture leads to loss of genetic diversity and heteroresistance(22). Additionally, in the  
84 normal course of *M. tuberculosis* infection, some bacteria exist as viable non-culturable  
85 persister organisms that are hypothesised to cause the high relapse rate seen following  
86 treatment of insufficient duration(23). These organisms are likely to be missed by any  
87 sequencing method reliant on culture.

88

89 WGS directly from sputum without enrichment is challenging(24). It has recently been  
90 improved by depleting human DNA during DNA extraction(25). We have previously reported  
91 the use of oligonucleotide enrichment technology SureSelect (Agilent, CA, USA) to sequence  
92 *M. tuberculosis* DNA directly from sputum(26) and demonstrated its utility in determining a  
93 rapid genetic drug resistance profile(27, 28).

94

95 It remains unclear to what extent WGS of cultured *M. tuberculosis* samples underestimates  
96 the genetic diversity of the population in sputum samples. One previous study of 16 patients  
97 did not identify increased genetic diversity in *M. tuberculosis* DNA sequenced directly from  
98 sputum compared to DNA from culture(25), whereas another study of mostly drug  
99 susceptible patients showed sequencing directly from sputum identified a slight excess of  
100 HAs relative to culture(27). Here we reanalyse heterozygous alleles (HAs) present in that  
101 study(27) in addition to newly collected samples from patients with MDR-TB, use a more  
102 sensitive analysis to measure overall within-sample genetic diversity and further explore the  
103 genomic location of the additional diversity identified.

104

## 105 Results

106

### 107 Patient Characteristics and Drug Susceptibility Testing

108

109 Whole genome sequences were obtained for 39 patients from both mycobacterial growth  
110 indicator tube (MGIT) culture and direct sputum sequencing. The patients were  
111 predominantly of black African ethnicity (80%) and 50% were HIV positive (Table 1). First-  
112 line phenotypic drug susceptibility testing (DST) results identified 22 patients with MDR-TB

113 and two with rifampicin monoresistance. In addition there were three isoniazid  
114 monoresistant patients and ethambutol resistance was detected in 8 patients. Second-line  
115 phenotypic DST was performed for patients with rifampicin-resistant or MDR-TB and  
116 identified one case of kanamycin resistance (Table 2).

117

118 We observed greater median coverage depth in sputum-derived sequences than MGIT  
119 sequences (164.3 vs 136.6,  $p=0.068$ ). A genotypic susceptibility profile was determined by  
120 evaluating MGIT WGS for consensus-level RAVs using a modified version of a publicly  
121 available list(29). Genotypic RAVs predicted all rifampicin phenotypic resistance and >90% of  
122 isoniazid phenotypic resistance. Ethambutol genotypic RAVs were poorly predictive of  
123 phenotypic resistance in line with findings from other studies(30) (Table 2). The patient with  
124 kanamycin phenotypic resistance was correctly identified by an *rrs* a1401g RAV. No full  
125 phenotypic fluoroquinolone phenotypic resistance was identified, but several colonies from  
126 patient F1013 did grow in the presence of ofloxacin (although not enough to be classified as  
127 resistant). The consensus sequences from this patient harboured a *gyrB* E501D mutation  
128 which is believed to confer resistance to moxifloxacin but not other fluoroquinolones, which  
129 may explain the borderline phenotypic DST result(31).

130

### 131 **Genetic Diversity**

132

133 To compare consensus sequences from sputum and MGIT, a WGS consensus sequence-level  
134 maximum likelihood phylogenetic tree was constructed (Supplementary Material: Figure 1).  
135 Four previously sequenced strains from KwaZulu-Natal were included(32). As expected, all  
136 paired sequences were closely related, with a mean difference of 1.30 (range 0-9) single

137 nucleotide polymorphisms (SNPs). Samples from patients F1066 and F1067 were closely  
138 related with only one consensus-level SNP separating all four consensus sequences. There  
139 was no obvious epidemiological link between these patients (although this study was not  
140 designed to collect comprehensive epidemiological information) and they lived 20km apart  
141 in Durban. However, both patients were admitted contemporaneously to an MDR  
142 treatment facility and sampled on the same day. DNA extraction and sequencing occurred  
143 on different runs so the close genetic linkage may represent direct transmission within a  
144 hospital setting, a community transmission chain or an unlikely cross-contamination during  
145 sample collection.

146

147 Having established congruence between sputum and MGIT sequences at the consensus  
148 level we then compared genetic diversity by DNA source. We first defined a threshold for  
149 calling variants present as heterozygous alleles (HAs) in our entire dataset by using a range  
150 of minimum read count frequencies as described in the methods (Figure 1). Below a  
151 minimum of five supporting reads there was an exponential increase in the number of HAs  
152 identified, which may be indicative of the inclusion of sequencing errors. To reduce this risk,  
153 we used a threshold of a minimum of five supporting reads.

154

155 Genetic diversity may occur because of within-host evolution or mixed infection. To identify  
156 mixed infection we used a molecular barcode(33) to scan all HAs for a panel of 413  
157 phylogenetic SNPs that can resolve *M. tuberculosis* into one of seven lineages and 55 sub-  
158 lineages. We found three phylogenetic SNPs among the HAs. In all cases the heterozygous  
159 phylogenetic SNP originated from the same sublineage as other SNPs present at 100%  
160 frequency, and there were no cases of HAs indicating the presence of more than one lineage

161 or sublineage. This suggests that the genetic diversity identified is mostly or exclusively due  
162 to within-host evolution, although there remains a small possibility that mixed infections  
163 with two strains from the same sub-lineage could have occurred.

164

165 As a first step to comparing diversity between sputum and MGIT sequenced samples we  
166 looked at the location of genetic diversity within the *M. tuberculosis* genome. Variants were  
167 called in the MGIT and sputum sequences for each patient and classified as present in MGIT  
168 only, sputum only or shared (present in both). HAs were widely dispersed across the  
169 genome at similar sites in both sputum and MGIT samples but some genes had multiple HAs  
170 (Table 3). The highest genetic diversity was found in the ribosomal RNA (rRNA) genes (*rrs*  
171 and *rrl*) with 358 HAs, of which 98.6% were only found in sputum-derived sequences.

172

173 As rRNA contains regions that are highly conserved across bacteria, it was considered a  
174 possibility that SureSelect baits targeting rRNA genes were capturing both *M. tuberculosis*  
175 and other bacterial species. To evaluate this, metagenomic assignment was performed on  
176 all reads. Sampling reads not assigned to *M. tuberculosis* (i.e. presumed contaminants from  
177 other bacteria) and performing a BLAST search against *M. tuberculosis* 16S and 23S rRNA  
178 genes indicated that a sizeable proportion of these reads from directly sequenced sputum  
179 had a BLAST hit of at least 30 bases (median 11% v 0% of equivalent reads from MGIT  
180 sequencing,  $p < 0.001$ , Supplementary Material: Figure 2). The taxonomic assignment of  
181 these reads were indeed typical of genera composing the oral flora, with a high  
182 representation of *Actinomyces*, *Fusobacterium*, *Prevotella*, and *Streptococcus*  
183 (Supplementary Material: Figure 3).

184

185 This supported the hypothesis that the baits may enrich rRNA from other organisms so rRNA  
186 genes were excluded from further analysis. The difference in diversity between sputum and  
187 MGIT sequences can be explained by the selective nature of MGIT media which will enrich  
188 *M. tuberculosis* sequences. Importantly the frequency of HAs in other highly diverse genes  
189 between sequencing strategies was more balanced (Table 3). Pertinently seven of these  
190 genes (*Rv1319c*(34), *lppB*(35), *Rv2082*(35), *ppsA*(34, 36), *ponA1*(36), *lppA*(37), and *pkc12*(35,  
191 36)) with high numbers of HAs have been previously identified as highly diverse in  
192 comparative genomic studies suggesting the detected HAs are not artefactual. The  
193 frequencies at which HAs in these genes were present in MGIT and sputum is shown in  
194 Supplementary Material Figure 4.

195

196 After confirming the absence of mixed infections and removing rRNA gene sequences we  
197 compared the frequency of HAs in sputum and MGIT. There were 2048 variants across the  
198 dataset that were present as a HA in either MGIT, sputum or both sequences (Table 4).  
199 Variants present in both MGIT and sputum derived sequences were more likely to be  
200 present as a HA in the sputum-derived sequence (3.2% v 1.9%,  $p < 0.0001$ ). Of the other  
201 variants present as HAs, 821 were unique to direct sputum sequencing and 153 were unique  
202 to MGIT sequencing (Table 4). Variants found only in sputum were more likely to be  
203 heterozygous than those found only in MGIT or in both ( $p < 0.0001$ ). The distribution of HAs  
204 by patient is shown in Figure 2A. HAs found only by one modality were more likely to be  
205 SNPs than shared HAs, where the majority were insertions or deletions. The ratio of non-  
206 synonymous to synonymous HAs was similar for those that were shared or MGIT only, but  
207 was lower for sputum only HAs. Frameshift mutations were most prevalent among shared  
208 HAs (Table 4).

209

210 To confirm our findings of increased diversity in sputum we calculated mean within-sample  
211 diversity ( $H$ ), excluding rRNA genes and repeat regions (see methods). The mean diversity  
212 was significantly greater in sputum than MGIT-derived sequences (Figure 2B:  $0.116 \pm 0.078$  v  
213  $0.054 \pm 0.026$ , mean  $H_{\text{sputum}}/H_{\text{MGIT}} = 2.66$ ,  $p = 3.0 \times 10^{-5}$ ).

214

### 215 **Genetic diversity in drug resistance genes**

216

217 HAs in drug resistance-associated regions, including promoters and intergenic regions, were  
218 individually assessed. Five of the 39 patients had RAVs present as HAs in at least one gene,  
219 which are shown in Table 5. F1002 had three compensatory mutations in *rpoC* present at  
220 HAs in both sequences. F1007 had high-level phenotypic isoniazid resistance despite wild  
221 type *katG* and *inhA* genes, but did have two *ahpC* promoter variants present as HAs. Neither  
222 of these variants are reported frequently but both have been previously associated with  
223 resistance in limited numbers of samples(38). As described above F1066 and F1067 were  
224 highly related with only one consensus SNP difference between all four sequences. Both had  
225 phenotypic high level isoniazid resistance with no consensus-level *katG* or *inhA* mutation,  
226 but had frameshift *katG* mutations present as HAs which have the potential to cause  
227 resistance(39). F1066 and RF021 had *Rv1979c* and *pncA* mutations respectively at low  
228 frequency in sputum only which have the potential to confer phenotypic resistance to  
229 clofazimine (*Rv1979c*) and pyrazinamide (*pncA*), although no phenotypic testing was  
230 performed for these drugs.

231

## 232 Discussion

233

234 In this study we whole genome sequenced DNA from sputum and MGIT culture in paired  
235 samples from 39 patients and compared within-patient genetic diversity of the bacterial  
236 genome identified from each source. All paired sequences were closely related at the  
237 consensus level, and WGS predicted phenotypic drug susceptibility with over 90% sensitivity  
238 and specificity for rifampicin and isoniazid in line with published data(40).

239

240 The understanding of within-patient *M. tuberculosis* genetic diversity is becoming  
241 increasingly important as the detection of rare variants has been shown to improve the  
242 correlation between phenotypic and genotypic drug resistance profiles(18) and can identify  
243 emerging drug resistance(11, 12). Here we have demonstrated that significantly more  
244 genetic diversity is identified by WGS performed directly from enriched sputum than MGIT  
245 culture. Not including a culture step avoids the introduction of bias towards culture-adapted  
246 subpopulations and the impact of random chance and is also likely to incorporate DNA from  
247 viable non-culturable mycobacteria. A reduction in genetic diversity has previously been  
248 shown with sequential *M. tuberculosis* subculture(19, 22), but was not confirmed by a study  
249 performing WGS directly from sputum(25). However, the 16 paired sputum and MGIT  
250 samples compared by Votintseva(25) had a minimum of 5x coverage compared to a  
251 minimum 40x coverage in this study, and were likely to contain less genetic material as they  
252 were surplus clinical rather than dedicated research samples.

253

254 We found that the rRNA genes have high levels of diversity in sputum samples, but believe  
255 this is due to non-mycobacterial DNA hybridising to the capture baits — a conclusion borne

256 out by the taxonomic assignment of reads aligning to these genes in common oral bacteria.  
257 We therefore exclude these from further analysis, and recommend others using enrichment  
258 from sputum do similarly. We use two methods to evaluate within-sample *M. tuberculosis*  
259 genetic diversity. First, we demonstrate increased diversity when sequencing directly from  
260 sputum with significantly more unique heterozygous alleles (HAs) than sequencing from  
261 MGIT culture. We also observed significantly higher genetic diversity in sputum-derived  
262 sequences by comparing the Shannon diversity of variable sites across pairs of samples.  
263  
264 Many of the genes with high levels of within-sample diversity are also reported to be targets  
265 for convergent evolution, independently accumulating similar mutations on a global scale.  
266 This implies that diversity seen on a macroevolutionary scale has a basis in microevolution,  
267 and reinforces the importance of accurately characterising the biological function of these  
268 genes and their products to aid the identification of new therapeutic targets. Two-thirds of  
269 the patients with MDR-TB had already been treated for drug-sensitive TB, and the diversity  
270 identified in sputum samples may therefore represent early adaptation to drug pressure.  
271 Importantly, as direct sputum sequencing does not rely on live mycobacteria, DNA from  
272 recently killed *M. tuberculosis* is likely to also be sequenced, meaning that recent genomic  
273 mutations are likely to be represented as HAs.  
274  
275 In four patients, RAVs present as HAs provided a likely genotypic basis for otherwise  
276 unexplained phenotypic resistance. Given the small total number of resistance mutations in  
277 this study, the excess of heterozygous known RAVs in directly sequenced sputum is not  
278 statistically significant. However the presence of heterozygous RAVs in both MGIT and  
279 sputum sequences reinforces the biological importance of these mutations.

280

281 A limitation of this study is that it can be difficult to distinguish low frequency variants from  
282 sequencing error. Ideally low frequency variants could be confirmed by resequencing the  
283 same DNA samples. To reduce the risk of sequencing errors yet still identify genetic diversity  
284 we used the lowest minimum read threshold at which the number of HAs remained stable.  
285 Also, it is reassuring that of all fixed and heterozygous variants called, more than 93% were  
286 identified from both DNA sources.

287

## 288 **Conclusions**

289

290 Directly sequencing *M. tuberculosis* from sputum is able to identify more genetic diversity  
291 than sequencing from culture. Understanding within-patient genetic diversity is important  
292 to understand bacterial adaptation to drug treatment and the acquisition of drug resistance.  
293 It also has potential to identify low frequency RAVs that may further enhance genotypic-  
294 phenotypic drug resistance correlation.

295

## 296 **Methods**

297

### 298 **Patient enrolment**

299 Adult patients presenting with a new diagnosis of sputum culture-positive TB were included  
300 in the study. Patients were recruited in London, UK (n=15) and Durban, South Africa (n=24).  
301 All patients recruited in Durban were Xpert MTB/RIF (Cepheid, CA, USA) positive for  
302 rifampicin resistance. Two sputum samples were collected prior to initiating treatment, with

303 one inoculated into mycobacterial growth indicator tube (MGIT) culture (BD, NJ, USA) and  
304 the other used for direct DNA extraction.

305

### 306 **Ethics, Consent and Permissions**

307

308 All patients gave written informed consent to participate in the study. Ethical approval for  
309 the London study was granted by NHS National Research Ethics Service East Midlands—  
310 Nottingham 1 (reference 15/EM/0091). Ethical approval for the Durban study was granted  
311 by University of KwaZulu-Natal Biomedical Research Ethics Committee (reference  
312 BE022/13).

313

### 314 **Microbiology**

315 MGIT samples were incubated in a BACTEC MGIT 960 (BD, NJ, USA) until flagging positive.  
316 Phenotypic DST data for London samples were those provided to treating hospitals by Public  
317 Health England. Phenotypic DST for Durban samples was performed using the solid agar  
318 proportion method (Supplementary Material: Methods).

319

### 320 **DNA extraction and sequencing**

321 Positive MGIT tubes were centrifuged at 16,000g for 15 minutes and the supernatant  
322 removed. Cells were resuspended in phosphate-buffered saline before undergoing heat  
323 killing at 95°C for 1 hour followed by centrifugation at 16,000g for 15 minutes. The  
324 supernatant was removed and the sample resuspended in 1mL sterile saline (0.9% w/v). The  
325 wash step was repeated. DNA was extracted with mechanical ribolysis before purification

326 with DiaSorin Liaison Ixt (DiaSorin, Italy) or CTAB(41). NEBNext Ultra II DNA (New England  
327 Biolabs, MA, USA) was used for DNA library preparation.

328

329 Sputum samples for direct sequencing were similarly heat killed processed as for MGIT  
330 samples. DNA extraction was performed with mechanical ribolysis followed by purification  
331 using DiaSorin Liaison Ixt (DiaSorin, Italy) or DNeasy blood & tissue kit (Qiagen,  
332 Germany)(41). Target enrichment was performed using SureSelect with a custom-designed  
333 bait set providing coverage of the entire *M. tuberculosis* genome as described  
334 previously(27). Batches of 48 multiplexed samples were sequenced on a NextSeq (Illumina,  
335 CA, USA).

336

### 337 **Bioinformatic analysis**

338 Bioinformatic analysis was performed with CLC Genomics Workbench v11.0 (Qiagen,  
339 Germany). DNA sequence reads were aligned to an H37Rv reference genome as detailed in  
340 the Supplementary Material Methods section (GenBank accession NC\_000962.3). All  
341 samples had minimum 98% 1x reference genome coverage and mean coverage depth 40x  
342 across the genome. Variants falling within or near hypervariable elements were excluded  
343 (Supplementary Material: Table 1). A consensus sequence was extracted and used to  
344 determine the genotypic drug susceptibility profile. To construct the maximum likelihood  
345 phylogenetic tree, variants were called against the reference genome using VarScan v2.3.9  
346 (Supplementary Material: Methods).

347

348 For the initial analysis of genetic diversity, variants were included if supported by  $\geq 2$  reads,  
349 with  $\geq 1$  forward and reverse read. The minimum supporting read threshold was increased in

350 a stepwise fashion from 2 to 20. Further analyses were performed on variant tracks where  
351 variants were supported  $\geq 5$  supporting reads including  $\geq 1$  forward and reverse read.

352

353 To compare diversity between paired samples, we first mapped reads to the reference  
354 genome using bwa mem v0.7.12(42). After verifying all samples had adequate coverage with  
355 qualimap(43) (mean  $\pm$  standard deviation coverage at 10x:  $98.0 \pm 1.8\%$ ) and realigning  
356 indels, variants were called with HaplotypeCaller in GATK v3.3.0(44) (Supplementary  
357 Material: Methods). The gvcf files were combined for each pair of samples with  
358 CombineGVCFs in GATK then screened to remove sites in variable regions and rRNA genes  
359 with vcfintersect in vcflib, resulting in 39 paired gvcf files containing allele depths at variable  
360 positions for diversity analysis.

361

### 362 **Metagenomic assignment**

363 Sequencing reads were classified using Kraken v0.10.6(45) against a custom Kraken  
364 database previously constructed from all available RefSeq genomes for bacteria, archaea,  
365 viruses, protozoa, and fungi, as well as all RefSeq plasmids (as of September 19<sup>th</sup> 2017) and  
366 three human genome reference sequences(46). The size of the final database after shrinking  
367 was 193 Gb, covering 38,190 distinct NCBI taxonomic IDs.

368

369 To assess the proportion of contaminating reads that could generate spurious diversity  
370 when mapped to *M. tuberculosis* ribosomal genes, we randomly subsampled 100 reads  
371 taxonomically assigned as non-*M. tuberculosis* and performed a BLAST search with blastn  
372 v2.2.28(47) against rRNA genes from the H37Rv reference genome. We only analysed hits of  
373 at least 30 bases.

374

## 375 **Statistics**

376 Statistical analyses were performed with Prism v7.0 (Graphpad, CA, USA). The number of  
377 HAs in paired samples were compared using a two-tailed Wilcoxon matched-pairs signed  
378 rank test. Numbers of HAs found between groups were compared with chi-squared.

379

380 Within-sample diversity ( $H$ ) was calculated using Shannon diversity from the allele  
381 frequencies ( $p$ ). The Shannon index ( $H_n$ ) expresses the positional entropy at each position  
382 ( $n$ ), with the mean positional entropy ( $H$ ) indicating greater within-sample diversity:

$$H = \sum_n H_n = \sum_n \sum_{i \in \{A,C,G,T\}} p_{n,i} \log(p_{n,i})$$

383 To make a fair comparison for each pair of samples, after removing indels, sites were  
384 included if they contained a variant in at least one and had a depth coverage  $\geq 30$  in both.  
385 We found that the depth coverage cutoff had no qualitative effect on the conclusions. The  
386 difference in mean within-sample diversity depending on DNA source was compared with a  
387 two-tailed Wilcoxon matched-pairs signed rank test.

388

## 389 **Abbreviations**

390

DST	drug susceptibility testing
HA	heterozygous allele
MDR-TB	multidrug resistant-tuberculosis
MGIT	mycobacterial growth indicator tube

RAV	resistance-associated variant
rRNA	ribosomal RNA
SNP	single nucleotide polymorphism
TB	tuberculosis
WGS	whole genome sequencing

391

392

393

394 **Declarations**

395

396 **Ethics approval and consent to participate**

397 All patients gave written informed consent to participate in the study. Ethical approval for  
398 the London study was granted by NHS National Research Ethics Service East Midlands—  
399 Nottingham 1 (reference 15/EM/0091). Ethical approval for the Durban study was granted  
400 by University of KwaZulu-Natal Biomedical Research Ethics Committee (reference  
401 BE022/13).

402

403 **Consent for publication**

404 Not applicable

405

406 **Availability of data and materials**

407 Original fastq files are available at NCBI Sequence Read Archive with BioProject reference  
408 PRJNA486713: <https://www.ncbi.nlm.nih.gov/bioproject/PRJNA486713/>

409

410 **Competing interests**

411 The authors declare that they have no competing interests.

412

413 **Funding**

414 Camus Nimmo is funded by a Wellcome Trust Research Training Fellowship reference  
415 203583/Z/16/Z. This work was additionally funded by National Institute for Health Research  
416 via the UCLH/UCL Biomedical Research Centre (grant number BRC/176/III/JB/101350) and  
417 the PATHSEEK European Union's Seventh Programme for research and technological

418 development (grant number 304875). The funding bodies had no input on study design,  
419 analysis, data interpretation or manuscript writing.

420

421 **Authors' contributions**

422 Study conception: JB, ASP

423 Data collection: CB, KB

424 Analysis and interpretation: CN, LPS, RD, RW

425 Drafting of manuscript: CN, LPS

426 Revision of manuscript: FB, JB, ASP

427 Final approval of manuscript: CN, LPS, RD, RW, KB, CB, JB, FB, ASP

428

429 **Acknowledgements**

430 The authors would like to thank Sashen Moodley, Ashentha Govender and Colin Chetty in

431 the Microbiology Core, Africa Health Research Institute.

432 **Tables**

Black African	28/35	80.0%
Caucasian	4/35	11.4%
<b>HIV positive</b>	19/38	50.0%
CD4 count (median)	296.5*	17 – 707
On antiretroviral therapy at time of diagnosis	8/19**	42.1%

434

435 Table 1. Baseline patient characteristics for 39 patients (or as otherwise specified where  
436 data were missing). \*Data missing for 1 patient.

437

438

<b>Drug</b>	<b>Resistance by phenotypic DST</b>	<b>Resistance by genotypic DST</b>	<b>Genotypic DST sensitivity</b>	<b>Genotypic DST specificity</b>
<b><i>First-line drugs</i></b>				
Rifampicin	24/37 (64.9%)	24/39	24/24 (100%)*	24/24 (100%)
Isoniazid	25/37 (67.6%)	24/39	23/25 (92.0%)	23/24 (95.8%)
Ethambutol	8/37 (21.6%)	17/39	8/8 (100%)	8/17 (47.1%)
<b><i>Second-line drugs</i></b>				
Ofloxacin	0/24 (0.0%)	1/24	N/A	0/1 (0%)**
Kanamycin	1/24 (4.2%)	1/24	1/1 (100%)	1/1 (100%)

439

440 Table 2. Phenotypic and genotypic drug susceptibility testing (DST) results and sensitivity  
 441 and specificity of genotypic DST relative to phenotypic DST. Phenotypic DST available for  
 442 first-line drugs for 37 of the 39 patients, and for second-line drugs for 24 patients who  
 443 demonstrated rifampicin drug resistance. \*In two directly-sequenced sputum samples  
 444 rifampicin RAVs were missed due to low coverage, although they were identified in the  
 445 corresponding MGIT sample. \*\*This sample had <1% of colonies grow in the presence of  
 446 ofloxacin, so is categorised as sensitive but may have low-level or heteroresistance to  
 447 fluoroquinolones (see main text).

448

Gene	Heterozygous Allele Count				Gene length (base pairs)	Hypothesised gene function
	Shared	MGIT only	Sputum only	Total

449

450 Table 3. Genes with the most heterozygous alleles (HAs) identified across the entire dataset.

451

452

	Shared variants	MGIT only variants	Sputum only variants	Total
<i>All variants vs H37Rv (fixed or heterozygous)</i>				
Total variants	33 153	1162	1217	35532
<i>Variants vs H37Rv present as heterozygous alleles (HAs) only</i>				
Total variants present as HAs (% of total variants)	MGIT 645 (1.9%) Sputum 1074 (3.2%)	153 (13.2%)	821 (67.5%)	2048 (5.8%)
Median HAs per sample	21	3	15	40
Variant type (% all HAs)				
SNP	500 (46.6%)	127 (83.0%)	708 (86.2%)	1335 (65.2%)
MNP	12 (1.1%)	1 (0.7%)	24 (2.9%)	37 (1.8%)
Insertion	303 (28.2%)	8 (5.2%)	31 (3.8%)	342 (16.7%)
Deletion	259 (24.1%)	16 (10.5%)	57 (6.9%)	332 (16.2%)
Replacement	0 (0.0%)	1 (0.7%)	1 (0.1%)	2 (0.1%)
Coding change (% all HAs)				
Non-synonymous	395 (36.8%)	79 (51.6%)	318 (38.7%)	792 (38.7%)
Synonymous	159 (14.8%)	32 (20.9%)	171 (20.8%)	362 (17.7%)
Intergenic	520 (48.4%)	42 (27.5%)	332 (40.4%)	894 (43.7%)
Non-synon/synon ratio	2.48	2.47	1.86	2.19
Stop codon (% of all non-synonymous HAs)	4 (1.0%)	1 (1.3%)	9 (2.8%)	14 (1.8%)
Frameshift (% of all non-synonymous HAs)	185 (46.8%)	19 (24.1%)	47 (14.8%)	251 (31.7%)

453

454 Table 4. Variants identified in MGIT derived, sputum derived, or both sequences from paired  
455 samples. Values given represent totals for the 39 paired samples. SNP = single nucleotide  
456 polymorphism; MNP = multi-nucleotide polymorphism.  
457

458

Patient ID	Phenotypic resistance	Mutation	Frequency (MGIT/sputum)	Description
F1002	Rifampicin	<i>rpoB</i> S450L	100%/100%	High confidence resistance mutation
F1002	Rifampicin	<i>rpoC</i> G332R(48)	82.6%/21.7%	Putative compensatory mutations
F1002	Rifampicin	<i>rpoC</i> L516P(48)	12.7%/7.7%	
F1002	Rifampicin	<i>rpoC</i> P1040S(49)	21.7%/12.3%	
F1007	Isoniazid (high)	<i>ahpC</i> c-52t(38)	60.0%/50.7%	Rare, have been associated with resistance
F1007	Isoniazid (high)	<i>ahpC</i> g-48a(38)	28.6%/30.3%	
F1061	Rifampicin	<i>rpoB</i> H445D	16.1%/0.0%*	High confidence resistance mutation
F1061	Rifampicin	<i>rpoB</i> S450W	84.4%/0.0%*	High confidence resistance mutation
F1066	Isoniazid (high)	<i>katG</i> N218fs	0.0%/6.9%	Possible resistance mutations, not previously described
F1066	Clofazimine – not tested	<i>Rv1979c</i> G376D	0.0%/0.5%	
F1067	Isoniazid (high)	<i>katG</i> N218fs	10.7%/7.6%	
RF021	Pyrazinamide – testing failed	<i>pncA</i> Q122H	0%/2.5%	

459

460 Table 5. Resistance-associated variants present as heterozygous alleles (HAs). \*These  
461 mutations were also present in sputum but due to low coverage of the area (3 and 4 reads  
462 respectively) variant calling criteria were not met.

463

464

465 **Figure legends**

466

467 Figure 1. Variation in total number of heterozygous alleles (HAs) identified across all 39  
468 patients in sequences generated from sputum and MGIT depending on minimum supporting  
469 read count threshold. Direct sputum samples indicated by red squares, MGIT samples blue  
470 circles.

471

472 Figure 2. (A) Number of heterozygous alleles (HAs) found in directly sequenced sputum only  
473 (sputum), MGIT (MGIT) only or in both samples (shared) by patient. (B) Mean Shannon  
474 diversity at variable positions across pairs of samples ( $H$ ) as calculated for MGIT and  
475 sputum-derived sequences. Size of point indicates number of variable positions considered  
476 (see Methods).
