ABSTRACT

Respiratory syncytial virus (RSV) is a leading cause of lower respiratory tract infection (LRTI) and hospitalization in infants and children globally. Many observational studies have found an association between RSV LRTI in early life and subsequent respiratory morbidity, including recurrent wheeze of early childhood (RWEC) and asthma. Conversely, two randomized placebo-controlled trials of efficacious anti-RSV monoclonal antibodies (mAbs) in heterogenous infant populations found no difference in physician-diagnosed RWEC or asthma by treatment group. If a causal association exists and RSV vaccines and mAbs can prevent a substantial fraction of RWEC/asthma, the full public health value of these interventions would markedly increase. The primary alternative interpretation of the observational data is that
1. Background and meeting objectives

Respiratory syncytial virus (RSV) is a leading cause of lower respiratory tract infection (LRTI) and hospitalization in children globally, causing an estimated 33.1 million LRTI episodes, 3.2 million hospitalizations, and 118,000 deaths in 2015 [1]. An estimated 45% of all hospitalizations and deaths are in infants less than 6 months of age, with 99% of global RSV mortality occurring outside of North America and Europe. The only licensed monoclonal antibody (mAb) to prevent RSV LRTI (Synagis®, palivizumab) is recommended only in high-risk infants (e.g. preterm or with certain co-morbidities) and is cost prohibitive for low and middle-income countries (LMICs). There are no licensed vaccines for RSV; however, several candidate products (e.g., vaccines and mAbs) are in clinical development [2].

A long-standing question is whether RSV LRTI in early life causes subsequent recurrent wheeze of early childhood (RWEC) and asthma. The current evidence supporting a causal association between RSV and RWEC/asthma is mixed. Understanding whether prevention of RSV LRTI can lead to reductions in rates of RWEC and asthma will contribute important information to policy decisions regarding RSV vaccines and mAbs.

To shed light on this important question, the World Health Organization (WHO) undertook three activities. The first comprised an analysis of the sample size required to estimate the potential impact of RSV prevention by vaccines or mAbs on the subsequent development of RWEC in RCTs [3]. The second was a systematic review and meta-analysis that will be reported separately. Third was a convening of subject matter experts on February 12–13, 2019 in Geneva, Switzerland (Agenda and Participants in Appendix A). The objectives of the meeting were: (i) to evaluate the strength of the current evidence for a causal association between early life RSV LRTI and subsequent RWEC/asthma, (ii) to evaluate the evidence that future RSV vaccines/mAbs can reduce rates of RWEC/asthma, and (iii) to provide methodological guidance for future studies. This report summarizes the meeting.

2. Epidemiology of RSV LRTI

Epidemiological studies have shown that more than half of children experience their first RSV infection in the first 12 months of life and almost all will have had an infection by two years of age [4]. Involvement of the lower airways occurs in 15–50% of children with primary RSV infection, with 45% of LRTI occurring in the first 6 months of life [1,5]. Although children born preterm, with low birth weight, chronic lung disease, congenital heart disease, or immunosuppression have increased risk of severe disease, most children with RSV LRTI were born full-term and have no underlying illnesses [6,7]. RSV LRTI usually corresponds to a clinical diagnosis of bronchiolitis or pneumonia and is differentiated from RSV upper respiratory tract infection by lower chest wall indrawing, tachypnea, diffuse rhonchi, or wheezing [8]. Wheezing associated with the acute RSV LRTI episode can persist for up to 4 weeks (median 12 days) [9]. The case-fatality ratio for RSV LRTI is low (<1%) if a child receives supportive care in a timely manner, but can be as high as 9% in low-income countries [1].

3. Epidemiology of RWEC and childhood asthma

Wheeze, which can refer to both a clinical sign and a reported symptom, is an intrathoracic sound and a sign of airflow limitation [10]. A large proportion of young children experience viral-associated recurrent wheeze, a highly heterogeneous condition that is not always indicative of asthma [11]. Asthma represents a disease spectrum with multiple phenotypes and may present with respiratory signs and symptoms including wheeze. A clinical diagnosis of asthma in older children and adults requires a history of symptom patterns and evidence of variable expiratory airflow limitation, which can be assessed by different lung function testing methods [11]. Asthma has been identified by WHO as one of the most significant non-communicable diseases in people of all ages and a major source of global economic burden, with the highest rates of asthma mortality occurring in LMICs [12]. Estimates of global childhood asthma prevalence come from the International Study of Asthma and Allergies in Childhood (ISAAC), which uses a standardized questionnaire for parent-reported history of wheeze [13]. Latin America, North America and Australia/New Zealand have the highest asthma prevalence among children 6–7 years (17–22%), but it is believed that there are high rates of undiagnosed asthma globally [14].

According to the Global Initiative for Asthma, asthma can be challenging to diagnose in children less than six years of age for the following reasons: (1) many young children experience viral-associated recurrent wheezing in the absence of asthma, and (2) measurements of airway obstruction using spirometry are challenging to perform in this age group and can be normal between symptomatic episodes [11,15]. Global guidelines therefore recommend that asthma diagnosis in children less than six years of age be based on the presence of risk factors (e.g., family history of asthma/atopy, allergic sensitization) in combination with respiratory symptom patterns, response to therapeutic treatment trials, and the exclusion of alternate diagnoses [11]. As an alternative to spirometry, the forced oscillation technique (FOT) to measure respiratory system resistance and compliance has recently been shown to be a promising technique for the measurement of lung function in children as young as six weeks [16].

Asthma is believed to be caused by complex interactions between genes and the environment. Heritability estimates for
asthma range from 25 to 95% and numerous markers of asthma risk have been identified, most notably polymorphisms at the chromosome 17q21 locus [17,18]. Variable asthma prevalence among genetically similar populations living in different settings indicates that environmental influences are key in asthma development [19,20], and some environmental risk factors for asthma appear to have the greatest effects in individuals with specific genetic risk variants [21,22].

4. Biologic basis for an association between early life RSV LRTI and RWEC/asthma

An association between infant bronchiolitis and later development of asthma was first hypothesized in the late 1950s [23]. Subsequent experimental studies have shown that mice infected with RSV have sustained airway hyperreactivity and histologic changes characteristic of human asthma that persist after clearance of the virus [24], and that early life RSV infection impairs regulatory T-cell function and increases susceptibility to allergic airway disease [25,26]. In humans, increased RSV viral load [27] and disease severity [28–30] are associated with increased risk of RWEC and/or asthma in some studies but not in others [31,32]. In one infant cohort, a distinct nasal immune response pattern to acute RSV illness was associated with increased risk of subsequent wheeze [33].

It is not well understood why some otherwise healthy infants develop severe LRTI when infected with RSV. Potential explanations include infection with a more virulent RSV strain [37–39], an aberrant host immune response [34], and/or the presence of other pre-existent determinants of vulnerability, both genetic and environmental (e.g., smoke exposure in utero and early life, crowding, and day care attendance). If pre-existent determinants of vulnerability cause severe disease with RSV infection, it is possible that they may also be independently predictive of an increased risk of developing RWEC and asthma in childhood. Evidence in support of this theory is provided by a prospective cohort study that assessed passive respiratory mechanics after birth, prior to any LRTI event, and found lower lung compliance and higher resistance to be associated with increased risk for both RSV hospitalization and number of days with subsequent wheeze in the first year of life [35]. Host genetic studies of RSV illness ascribe a genetic component to risk for severe infection [36] and several shared markers of risk for both RSV LRTI and asthma have been identified [17,37,38]. Twin studies also suggest a shared genetic risk for both diseases [39–41].

5. Evidence for an association between early life RSV LRTI and RWEC/asthma

5.1. Observational studies

Most of the evidence for an association between early life RSV LRTI and subsequent RWEC and asthma comes from observational studies, of which only two have been conducted in LMICs [42,43]. These studies can be divided into two types: prospective studies that follow longitudinal cohorts of children forward in time, assessing them regularly for RSV LRTI and RWEC/asthma, and retrospective studies that use administrative databases to identify children who have had documented RSV LRTI and/or RWEC/asthma in the past.

The first type of prospective study is referred to here as a “medical event cohort study,” which defines exposure as an RSV LRTI inpatient or outpatient medical event, usually occurring within the first 1–2 years of life. Eligibility for enrollment into medical event cohort studies is therefore defined based on the known RSV LRTI exposure status. When studies compare this exposed group to those without RSV LRTI medical events, or to individuals hospitalized for a non-respiratory condition, many find a positive association between RSV LRTI and subsequent RWEC with odds ratios ranging from 3 to 36 [35,37,43–52] and between RSV LRTI and asthma with odds ratios ranging from 3–17 [35,42,53–61]. In contrast, studies that compare individuals with RSV LRTI to those with LRTI due to other respiratory pathogens (e.g., human rhinovirus and bocavirus) usually find no difference in the risk of subsequent RWEC/asthma [29,31,62–74], or find RSV LRTI to be negatively associated with these outcomes compared to the non-RSV LRTI exposed [75–84]. Several studies compared the same exposure group (with RSV LRTI medical events) to both types of comparison groups and found a positive association between RSV LRTI and RWEC/asthma when comparing exposed individuals to those without LRTI, but no significant association when compared to those with a non-RSV LRTI [37,42,53,54,76,77,85–89]. These studies suggest that LRTI due to some other respiratory viruses is as, or possibly more likely, to result in RWEC/asthma than RSV LRTI.

The second type of prospective study is a birth cohort study in which participants are enrolled in early infancy and prospectively surveilled for respiratory illnesses and RWEC/asthma outcomes. These include high-risk birth cohorts that enroll infants born preterm and/or with a family history of asthma or atopy [21,90–92] as well as cohorts of healthy, term infants [93–96]. Most compare children with RSV LRTI to those without LRTI of any type; some report positive associations with RWEC/asthma [91–93,95,97] and others find no association [21,90,94,98]. Those that compare risk of RWEC/asthma in children with RSV LRTI compared to those with a non-RSV LRTI have found mixed results [96] or no difference in risk between LRTI groups with respect to future RWEC/asthma [99,100].

A third type of prospective observational study follows non-randomized infants who received RSV mAbs [101–108] or RSV immunoglobulin [103] based on clinical indications and compares RWEC and asthma outcomes in this group to children with similar clinical profiles who did not receive RSV immunoprophylaxis. Some of these studies showed a reduction in RWEC in preschool aged children but no effect on outcomes measured at older ages [101,102,106], one found a reduction in RWEC in nonatopic but not in atopic children [104], and others found no difference in asthma by treatment status [107,108].

The association between RSV and RWEC/asthma can also be evaluated retrospectively, using administrative databases such as medical records. Administrative database studies have consistently shown associations between RSV LRTI hospitalization or unspecified bronchiolitis in early life and RWEC/asthma medical events in later life [32,109–113], although only one such study required laboratory confirmation of RSV [111]. A study of children with primary RSV LRTI hospitalization before 24 months of age found that rates of subsequent asthma hospitalizations were approximately 4-fold higher in children first hospitalized with RSV LRTI between 6 and 24 months of age compared to children first hospitalized with RSV LRTI between 0 and 3 months of age [110]. A twin database in Denmark showed no difference in asthma or lung function among monozygotic twins discordant for RSV hospitalization in early life [39–41].

5.2. Randomized intervention studies

Two placebo-controlled randomized controlled trials (RCTs) of RSV mAbs have assessed RWEC and/or asthma outcomes. The first trial was an RCT of palivizumab conducted in healthy preterm Dutch infants that showed a decrease in the number of days with parent-reported wheezing in the first year of life and
parent-reported current asthma at six years of age in the intervention group, but no difference in physician-diagnosed asthma or lung function at six years of age [114,115]. The second trial was an RCT of motavizumab, an efficacious next generation mAb that ultimately was not pursued for licensure. The motavizumab trial was conducted in healthy, term Native American infants and found no difference between treatment groups in the incidence of medically attended wheezing between one and three years of age [116].

5.3. Systematic reviews of the available evidence

Several systematic reviews [37,117–119] and two meta-analyses [120,121] have assessed the evidence for an association between RSV illness and subsequent RWEC and/or asthma. The most recent systematic review without meta-analysis was published in 2017 as a part of a series of publications from the REGAL (RSV evidence – a Geographical Archival of the Literature) study. It included 74 publications from the United States, Canada, and Europe (including Turkey and the Russian Federation) [117]. Key findings were that early life RSV LRTI is strongly associated with RWEC and asthma persisting at least through early childhood, and with reduced lung function and increased airway reactivity. Preterm birth, Down syndrome and congenital heart disease were identified as potential effect modifiers that increase the strength of the association. A meta-analysis published in 2013 included 20 publications from 15 unique studies and found that children with RSV LRTI in early life had significantly higher relative odds of wheeze and asthma in later life compared to those without RSV LRTI (OR 3.84 [95% CI 3.23, 4.58]) [120]. A second meta-analysis, published in 2019, included 41 observational studies and excluded immunoprophylaxis studies [121]. It found that compared to children without respiratory symptoms in infancy, those with laboratory confirmed RSV illness in the first year of life had higher relative odds of RWEC through three years of age (OR 3.05 [95% CI 2.50–3.71]) and between three and six years of age (OR 2.60 [95% CI 1.67–4.04]). Between six and twelve years of age, the relative odds of RWEC (OR 2.14 [95% CI 1.33–3.45]) and asthma (OR 2.95 [95% CI 1.96–4.46]) were both significantly greater in the RSV-exposed group. When the comparator group was infants with a non-RSV LRTI, there was no statistically significant association with subsequent RWEC or asthma for any of the age groups and when the comparator group was infants with human rhinovirus-associated LRTI, there was an inverse association with RWEC between three and six years of age (OR 0.41 [95% CI 0.20–0.83]). Finally, the WHO has commissioned a third systematic quantitative review and meta-analysis of epidemiologic and clinical trial data that will examine testable implications via differential misclassification if children with a history of RSV LRTI are more prone to be diagnosed clinically with RWEC/asthma and/or undergo testing for asthma, or if children in the comparator group have RSV LRTI that is not detected. Misclassification bias can also be introduced if parents of children with RSV LRTI are more likely to report or remember wheezing episodes, and likewise, if parents of children with asthma more readily recall early RSV illness. Another potential source of misclassification bias is that many studies do not define a clear ‘washout’ period after the acute RSV illness, raising the possibility that some wheezing associated with the acute primary RSV disease episodes are misclassified as respiratory sequelae.

Confounding can be another source of bias in observational studies. Studies that do not adequately control for risk factors for both RSV LRTI and RWEC/asthma such as age, prematurity, access to health care, co-morbidities, exposure to indoor air pollution and secondhand smoke, and genetic susceptibility may be subject to a confounding bias that overestimates the association. Insufficient understanding of the shared genetic susceptibility for RSV LRTI, RWEC and asthma (e.g. specific immune markers or genes) limits the possibility to control for genetic confounding in observational designs. One approach to control for genetic confounding is to study twins. Although their statistical power is limited by their small size, studies of monozygotic twins discordant for RSV hospitalization in infancy have not shown evidence of differences in asthma prevalence or lung function [39–41]. Another approach is to capitalize on a quasi-random exposure variation, such as temporal variation in viral strain virulence, or periodic absences of circulating RSV. A specific example of this occurs annually due to the seasonal peaks of RSV circulation in temperate climates whereby children born just before the RSV season are at maximal risk for severe disease during their first few months of life when RSV circulation peaks. A study in Tennessee found birth four months before the winter virus peak to be associated with the highest risk for developing asthma [109]. Although less prone to confounding by a shared predisposition, birth timing studies can be confounded by other seasonal phenomena, such as non-RSV respiratory pathogens, allergens and other environmental exposures.

Another consideration in interpreting observational studies is the choice of comparison group. As noted earlier, a positive association between RSV LRTI and subsequent RWEC/asthma is consistently observed in studies that compare this exposure group to a comparator group without any LRTI medical event, but not when comparing to individuals with an LRTI caused by a pathogen other than RSV. This could be interpreted as meaning that multiple respiratory viruses are causal agents for RWEC/asthma, that LRTI itself is a causal agent, or that the susceptibility to develop LRTI when infected with any respiratory virus is a marker of underlying predisposition for RWEC/asthma.

Finally, although some non-randomized studies of RSV immunoprophylaxis in high-risk infants have found a reduction in RWEC or better lung function in treated compared to untreated infants [101–103,105,106], the absence of randomization makes these studies subject to biases. Moreover, the population risk profiles and the methods to evaluate the outcomes varied considerably in these studies, making it challenging to draw inferences across them [122]. Lastly, the restriction to high-risk infants with a clinical indication for immunoprophylaxis limits the ability to generalize their results to the general infant population.

6. Methodological considerations in defining a causal relationship between RSV LRTI and RWEC/Asthma

6.1. Observational studies

Selection bias, information bias, and confounding can each affect observational studies of RSV and RWEC/asthma. Selection bias can occur if children with severe RSV disease are more likely than those with less severe RSV LRTI to be enrolled and retained in a cohort through the study period. Information bias can occur via differential misclassification if children with a history of RSV LRTI are more prone to be diagnosed clinically with RWEC/asthma and/or undergo testing for asthma, or if children in the comparator group have RSV LRTI that is not detected. Misclassification bias can also be introduced if parents of children with RSV LRTI are more likely to report or remember wheezing episodes, and likewise, if parents of children with asthma more readily recall early RSV illness. Another potential source of misclassification bias is that many studies do not define a clear ‘washout’ period after the acute RSV illness, raising the possibility that some wheezing associated with the acute primary RSV disease episodes are misclassified as respiratory sequelae.

Confounding can be another source of bias in observational studies. Studies that do not adequately control for risk factors for both RSV LRTI and RWEC/asthma such as age, prematurity, access to health care, co-morbidities, exposure to indoor air pollution and secondhand smoke, and genetic susceptibility may be subject to a confounding bias that overestimates the association. Insufficient understanding of the shared genetic susceptibility for RSV LRTI, RWEC and asthma (e.g. specific immune markers or genes) limits the possibility to control for genetic confounding in observational designs. One approach to control for genetic confounding is to study twins. Although their statistical power is limited by their small size, studies of monozygotic twins discordant for RSV hospitalization in infancy have not shown evidence of differences in asthma prevalence or lung function [39–41]. Another approach is to capitalize on a quasi-random exposure variation, such as temporal variation in viral strain virulence, or periodic absences of circulating RSV. A specific example of this occurs annually due to the seasonal peaks of RSV circulation in temperate climates whereby children born just before the RSV season are at maximal risk for severe disease during their first few months of life when RSV circulation peaks. A study in Tennessee found birth four months before the winter virus peak to be associated with the highest risk for developing asthma [109]. Although less prone to confounding by a shared predisposition, birth timing studies can be confounded by other seasonal phenomena, such as non-RSV respiratory pathogens, allergens and other environmental exposures.

Another consideration in interpreting observational studies is the choice of comparison group. As noted earlier, a positive association between RSV LRTI and subsequent RWEC/asthma is consistently observed in studies that compare this exposure group to a comparator group without any LRTI medical event, but not when comparing to individuals with an LRTI caused by a pathogen other than RSV. This could be interpreted as meaning that multiple respiratory viruses are causal agents for RWEC/asthma, that LRTI itself is a causal agent, or that the susceptibility to develop LRTI when infected with any respiratory virus is a marker of underlying predisposition for RWEC/asthma.

Finally, although some non-randomized studies of RSV immunoprophylaxis in high-risk infants have found a reduction in RWEC or better lung function in treated compared to untreated infants [101–103,105,106], the absence of randomization makes these studies subject to biases. Moreover, the population risk profiles and the methods to evaluate the outcomes varied considerably in these studies, making it challenging to draw inferences across them [122]. Lastly, the restriction to high-risk infants with a clinical indication for immunoprophylaxis limits the ability to generalize their results to the general infant population.

6.2. Randomized controlled trials of monoclonal antibodies

The greatest advantage of RCTs is that confounding by a shared predisposition for both the exposure and outcome should be eliminated. However, RCTs can be subject to misclassification bias, particularly if unmasking of the treatment assignment occurs before the end of follow up. There may have been such bias in the Dutch
palivizumab RCT that showed a decrease in parent-reported asthma at six years of age after unmasking had occurred, but no difference in more objective measures including physician-diagnosed asthma or lung function [114].

A limitation of RCTs of RSV mAbs and vaccines is that they require very large sample sizes to detect an association with most RWEC/asthma outcomes. A recent analysis used systematic reviews and expert opinions to test 81 sample size assumption scenarios, with risk ratios between maternal vaccination and recurrent wheezing ranging from 0.9 to 1.0 for 70% of the scenarios [3]. Scenarios were ranked according to plausibility, with 75% of plausible scenarios requiring a sample size greater than 30,000 and 47% requiring a sample size greater than 100,000 mother-infants per trial arm. According to this analysis, the two mAb RCTs described above, as well as a recently completed phase III maternal RSV vaccine trial (ClinicalTrials.gov ID: NCT02624947), would have been underpowered to find a statistically significant effect on RWEC and asthma.

7. Recommendations for future studies

This report summarizes many of the methodologic challenges faced by studies that aim to assess (1) whether there is a causal association between early life RSV LRTI and subsequent RWEC and asthma, or (2) whether an effective RSV preventive product could be expected to reduce the risk of subsequent RWEC/asthma. Recognizing these limitations, the participants discussed good practices for designing and analyzing future studies in order to maximize their contribution to the evidence base. This guidance is presented in Tables 1A and B and summarized below:

Observational studies: Additional observational studies using conventional designs were considered to be of little value in further elucidating the causal link between RSV LRTI and RWEC/asthma, with a few exceptions. Observational studies that would be of value are those that incorporate measures of neonatal immune function or pre-exposure lung function assessments, and those that involve quasi-random exposure to RSV in specific geographical settings.

Randomized controlled trials: RCTs were considered to be the least biased study design to assess both the questions of causal association and whether RSV preventive products can reduce subsequent RWEC/asthma, but they require investment in sufficiently powered individual trials and/or the use of standardized measures of exposure and outcome to allow pooling of data across multiple studies for meta-analyses.

Post-introduction studies: Given the large sample sizes required by RCTs, post-introduction studies conducted after RSV vaccines/mAbs are licensed and introduced into national programs were considered to be promising strategies to address these questions. Examples include pre-post ecological studies, case-control studies, and phased introduction studies. Pre-post studies, where population-level rates of RWEC/asthma before and after vaccine introduction are compared, offer a straightforward approach but are not recommended to address these questions due to important limitations. In addition to requiring high quality pre-introduction surveillance data, they are susceptible to bias due to temporal trends in disease prevalence. This is a particular risk for asthma outcomes because asthma prevalence is not constant within communities over time and secular trends in risk factors such as diet, antibiotic use, urbanization and air pollution can be difficult to control for [123]. Case-control studies that compare vaccination status in children with and without the outcome of interest are commonly used to evaluate vaccine effectiveness post-introduction. However, such case-control studies are often biased in that unvaccinated children differ from vaccinated children in ways that are related to the outcome of interest; in this case their propensity to be diagnosed with RWEC/asthma. Therefore, case-control studies to answer this question were not considered to be appropriate. Phased introduction, whereby a vaccine is sequentially introduced to defined geographic areas, offers the most promising design to address whether RSV preventive products can reduce the risk of subsequent RWEC/asthma. By comparing contemporaneous cohorts of RSV-vaccinated and unvaccinated children, phased introduction addresses year-to-year variability and minimizes confounding by temporal factors. Like pre-post studies, it requires a robust surveillance system to be in place prior to vaccine introduction and to be maintained throughout the follow-up period. It also requires that populations with early access to the vaccine do not differ in important ways from populations with delayed access to the vaccine (including with respect to exposure to environmental risk factors, such as air pollution), and that outcome ascertainment does not differ by introduction group. In some situations, the areas for vaccine introduction can be randomly assigned. Examples of this are WHO’s pilot programme for the RTS, S/AS01 malaria vaccine [124], the phased introductions of PCV in Mongolia [125], and hepatitis B vaccine in The Gambia [126].

Given the limitations of each approach, a combined strategy incorporating evidence from long-term follow up of randomized trials in addition to post-introduction data will likely be required to determine whether vaccines and mAbs reduce RWEC/asthma. A challenge of all prospective study designs is retaining participants throughout the 3–5 years of follow up that are required before outcomes can be assessed. Regardless of design, all studies conducting long-term follow up should assess the comparability of those who remain in the study to those who are lost to follow-up.

Finally, the meeting participants identified key variables, definitions and measurements that future studies assessing these questions should consider (Table 2). The participants recommended that the primary exposure of interest should be laboratory-confirmed RSV LRTI between birth and two years. Guidance for defining the exposure was aligned with advice from a previous WHO consultation that recommended using the Integrated Management of Childhood Illness (IMCI) definitions of LRTI [127], with inclusion of objective measures of severity such as tachypnea and oxygen saturation [128].

There was agreement that the primary long-term outcomes of early life RSV LRTI that are of public health interest are RWEC, measured until at least three years of age, and asthma, measured at six years of age or later, and that studies should prioritize medically attended outcomes using standard definitions. FOT is a promising tool for objective measures of lung function in infants and young children and can be considered for use in all settings, including LMICs [16]. In clinical trials, study personnel should remain masked to treatment allocation for the entire duration of follow up to minimize bias in the follow up of long-term outcomes, particularly since infants will have passed the critical age for immunization once the trial has ended. Objective measures of outcomes with blinded analysis should be prioritized.

Potential confounders are important to measure in observational studies to the extent possible but some, such as genetic susceptibility, are very difficult to control for. Simple, standardized data collection methods for all co-variates of interest are preferred, with birth weight, preterm birth, and family history of asthma and atopy identified as the highest priority. Finally, although studies are unlikely to be powered to detect effect modification, information about preterm birth, Down syndrome, and congenital heart disease should be collected if available.

■ Can measure outcomes longitudinally  
■ Can measure co-variates of interest prospectively                                                | ■ Observational, non-randomized  
■ Subject to biases  
■ Common predisposition (e.g., genetic confounder) cannot be ruled out  
■ Loss to follow-up  
■ Choice of comparison group can affect results (e.g., no LRTI vs. non-RSV LRTI) | Additional studies using this design offer limited potential for further insight and should only be done (1) if improved measurements of shared predisposition can be measured (e.g., genetic markers), (2) if they assess quasi-random exposures to RSV LRTI (e.g., birth timing) or (3) if lung function is measured before first RSV exposure |
| Retrospective cohort studies using administrative data | Short                         | Low to medium      | Large                | No                                    | ■ Large sample size available  
■ Can evaluate subgroups of interest and effect modification  
■ Can be done more quickly and with fewer resources compared to most other designs  
■ Randomized exposure  
■ Standardized exposure and outcome measurements make meta analyses possible  
■ Can measure co-variates of interest prospectively                                                  | ■ Observational, non-randomized  
■ Imprecise definitions of exposure and outcome are possible  
■ Subject to biases  
■ Some co-variates of interest may not be available  
■ Very large sample size required  
■ Requires several years of follow up  
■ RSV LRTI protection period may be limited to a few months (in the case of maternal vaccines and mAbs)  
■ Definitions may be difficult to standardize in practice across different settings  
■ Potential loss to follow up                                                                 | Additional studies using this design offer limited potential for further insight and should be limited to studies that can incorporate birth timing to reduce bias in the exposure variable. |
| Randomized controlled trials or vaccine probe studies | Long                          | High               | Large                | Yes                                   | ■ Randomized exposure  
■ Standardized exposure and outcome measurements make meta analyses possible  
■ Can measure co-variates of interest prospectively                                                   | ■ Observational, non-randomized  
■ Imprecise definitions of exposure and outcome are possible  
■ Subject to biases  
■ Some co-variates of interest may not be available  
■ Very large sample size required  
■ Requires several years of follow up  
■ RSV LRTI protection period may be limited to a few months (in the case of maternal vaccines and mAbs)  
■ Definitions may be difficult to standardize in practice across different settings  
■ Potential loss to follow up                                                                 | This design has greater potential to establish causal association than observational studies. Individual studies should be powered to assess an RWE/asthma outcome. If not possible, standardized assessments should be used so that data from multiple RCTs can be pooled for analysis. An absence of effect does not establish that there is not a causal relationship. Vaccination allocation should remain masked until the end of long-term follow-up. If this is not possible, a priority should be placed on objective measurement of outcomes with blinded analysis. |

\(^1\) Low and middle-income countries

\(^2\) A short amount of time is needed to accrue participants in case control studies, but recurrent wheeze and asthma outcomes cannot be assessed until several years after vaccination.
Table 2
Key variables, definitions and measurements for future studies of the association between RSV lower respiratory tract infection and subsequent recurrent wheeze of early childhood (RWEC) and asthma.

Defining the exposure:
- **Exposure period**: o Between birth and two years, may vary by study design
- **Microbiological confirmation**: o Assays that allow for identification of RSV viral strains (A/B) are optimal
- o Multiplex PCR assays should be used to identify co-infecting respiratory pathogens, when possible
- o RSV gene sequencing and RSV serology at 12 months of age in conjunction with methods above are lower priority, but can be considered along with the other diagnostic methods
- **Definition of lower respiratory tract infection (LRTI)**: o The LRTI clinical case definition should be based on Integrated Management of Childhood Illness (IMCI) criteria for acute lower respiratory infection
- o Both LRTI inpatient and outpatient events should be included since hospitalization criteria can vary widely by study setting
- **Measures of severity**: o The following should be collected: respiratory rate, oxygen saturation, temperature, auscultation, cough, subcostal retractions, and difficulty breast feeding/feeding
- o Quantitative measures should be recorded using a continuous scale to allow for flexibility in categorization that can be compared across settings
- o A combination of these variables can be used to generate severity scores that can be compared across settings

Defining the outcome:
- **Measuring RWEC and asthma**: o Objective measures should be prioritized, including medically attended outcomes and lung function testing
- o Parent/caregiver reports can provide useful supplemental information when standardized assessments are used; examples of Standardized Definitions include the 2019 Brighton Collaboration definitions for acute wheeze in the pediatric population
- o In randomized trials, caregivers and physicians should be masked to treatment group allocation
- o Continuous outcomes (e.g. number of medically attended wheezing events) should be reported whenever possible.
- o In LMIC settings with low literacy, phone calls are recommended over diaries. Audio and video clips can be used to standardize reporting
- o Medical costs and burden on the health system, absences from work and school, can be useful to collect depending on the setting
- **Measuring lung function**: o Forced oscillation technique with bronchodilation is more sensitive than spirometry for the detection of abnormal resistance, can be used in young children, and can be done in the field in LMIC settings
- **Follow up period**: o RWEC outcomes should be reported annually for each year of life, with follow up until at least three years of age
- o Asthma outcomes should be assessed at six years of age or later
- **High priority co-variates of interest**: o Birth weight, which can be a proxy for compromised lung function and development at birth
- o Preterm birth, which is associated with both RSV LRTI and RWEC/asthma, but can be difficult to ascertain in LMICs
- o Family history of asthma/atopy
- **Additional co-variates of interest**: o Co-infections with other respiratory pathogens
- o Other medically attended LRTIs
- o Vaccination status
- o Sex
- o Ethnic group
- o Timing of birth relative to the RSV season
- o Age at the time of first RSV LRTI illness
- o Smoke exposure (including maternal smoking during pregnancy, household smoking after birth, and ambient air pollution)
- o Mode of delivery (vaginal vs. caesarean section)
- o Access to health care
- o Vaccination status
- o Household crowding index
- o Nutritional status

Potential confounders and effect modifiers to measure
- Infants born preterm, with down syndrome or congenital heart disease

8. Policy considerations
The meeting participants agreed that, given the current knowledge of the potential public health benefit, RSV vaccine policy decisions should be based on the efficacy and impact against the spectrum of acute illness caused by RSV LRTI in infants and young children, with the primary focus being prevention of severe disease. Definitive data on the impact of RSV vaccines/mAbs on subsequent RWEC and asthma are unlikely to be available at the time vaccine policy recommendations are made. If high-quality, robust evidence does eventually support a preventive role of RSV vaccines/mAbs for RWEC/asthma, the additional longer term health and economic benefits related to RWEC/asthma prevention could contribute to policy-making in some countries.

9. Summary and conclusions
This WHO-sponsored meeting was convened to evaluate the current evidence for a causal association between RSV LRTI in young children and subsequent development of RWEC/asthma, to assess the potential for RSV vaccines and mAbs to reduce the risk of RWEC and asthma, and to provide guidance for future studies that are poised to address these questions. The evaluation of the evidence was focused on the body of epidemiological literature rather than the experimental data from animals and humans. Moreover, the application of causal modelling techniques to the epidemiologic data were not considered, but will be addressed in the forthcoming WHO commissioned systematic review and meta-analysis [129]. The meeting participants concluded that most
observational studies show an association between RSV LRTI and RWEC and asthma; however, the interpretation of these studies, as they were performed, is subject to potential measured and unmeasured biases. The most compelling counter-argument against a causal association is that there could be a shared predisposition for both severe RSV disease and RWEC/asthma and that having severe disease with an RSV infection is a marker of this predisposition. RCTs of RSV mAbs did not show efficacy against objective measures of RWEC/asthma, although they were not powered to do so.

After reviewing the evidence, the participants resolved that: (i) the current epidemiological evidence is inconclusive in establishing a causal association between RSV LRTI and RWEC/asthma, (ii) the evidence does not establish that RSV mAbs and vaccines are likely to have a substantial effect on these outcomes and (iii) the prevention of severe, acute RSV disease in young children, a well-established, substantial public health burden, should continue to be the highest priority for policy-setting bodies deliberating on RSV vaccine and mAb recommendations, regardless of their impact on subsequent RWEC and asthma (Panel 1). RSV vaccine impact and economic models should limit prevention of RWEC/asthma to sensitivity analyses, and RSV vaccine policy decisions should not include impacts on RWEC/asthma prevention.

Nonetheless, the participants considered that the high burden of RWEC and asthma justifies the continued study of the association between these two conditions, and that a better understanding of the association could contribute to establishing the public health value of RSV vaccines and mAbs. Regardless of whether a causal association exists, the burden of RWEC/asthma in LMICs needs to be elucidated and benchmarked to other public health priorities. Future epidemiological studies that examine the association should follow good practice guidance (Tables 1A and B) using standardized methods to collect and define key variables (Table 2). RCTs of RSV vaccines and mAbs provide the best opportunity to probe whether a causal association exists in an unbiased way, and such studies may consider long-term follow-up of participants to measure RWEC, and if possible, asthma, using standardized methods to allow for pooled analysis. Moreover, eventual large-scale introduction of RSV preventive products might create opportunities to assess the causal association between RSV and RWEC/asthma at a population level. The design of post-introduction evaluations and the development of baseline surveillance platforms should be considered prior to introductions, particularly in LMICs where data on the burden of RWEC/asthma are limited.

Both RSV associated LRTI and RWEC/asthma confer a substantial disease burden in children globally. To identify a single intervention, such an RSV vaccine or mAb, that lessens the burden of both diseases would be a fortuitous public health success. Efforts should continue to better understand whether this can be achieved. Nonetheless, lack of conclusive evidence for a dual preventive impact should not slow the pursuit of new preventive approaches independently targeting each of these important diseases of childhood.

Declaration of Competing Interest

The authors declare the following financial interests/personal relationships which may be considered as potential competing interests: LB has regular interaction with pharmaceutical and other industrial partners. He has not received personal fees or other personal benefits. He is the founding chairman of the ReSVINET Foundation. JAE has served as a consultant to Sanofi Pasteur and Meissa Vaccines and her institution receives support from Novavax, AstraZeneca, Merck, and GlaxoSmithKline. LLH reports research grants to her institution from Novavax, Merck, GSK, and Pfizer. TVH receives funding relevant to the submitted work from the National Institutes of Health and the WHO and served on the Pfizer RSV Infant/Maternal Health External Advisory Board in 2019. HN has received grant funding from Bill and Melinda Gates Foundation, Sanofi Pasteur, World Health Organization and Innovative Medicines Initiative. HN has received honoraria and speaker fees from Sanofi Pasteur, Abbvie and Janssen. EAFS reports grant support and personal fees in the last 36 months from AstraZeneca Inc., Merck & Co., Regeneron Inc., and Pfizer Inc.; grant support from Novavax; and personal fees from Roche Inc. AbbVie Inc., and Alere Inc.

Acknowledgments

We are grateful to Martin Friede (World Health Organization), Katherine O’Brien (World Health Organization), Prachi Vora (Bill & Melinda Gates Foundation) and Deborah Higgins (PATH) for their contributions to the meeting, and to Lien Anh Ha Do (Murdoch Children’s Research Institute, Melbourne, Australia) for her review of the manuscript draft.
Role of the Funding Source

This meeting was funded by a grant from the Bill & Melinda Gates Foundation (Global Health Grant OPP1114766) to the World Health Organization, which sponsored the meeting. Disclaimer: the views, findings, and conclusions in this report are those of the authors. They should not be construed to represent the positions or policies of the Bill & Melinda Gates Foundation or the World Health Organization, nor do they necessarily represent the official position of the US Centers for Disease Control and Prevention or the US Public Health Service.

AGENDA

Organizer: Daniel Feikin, WHO
