Abstract

Introduction: HIV self-testing (HIVST) is an alternative strategy for reaching population sub-groups underserved by available HIV testing services. We assessed individual factors associated with ever HIVST within a community-based programme.

Setting: Malawi.

Methods: We conducted secondary analysis of an endline survey administered under a cluster-randomised trial of community-based distribution of HIVST kits. We estimated prevalence differences and prevalence ratios (PR) stratified by sex for the outcome: self-reported ever HIVST.

Results: Prevalence of ever HIVST was 45.0% (475/1,055) among men and 40.1% (584/1,456) among women. Age was associated with ever HIVST in both men and women, with evidence of a strong declining trend across categories of age. Compared with adults aged 25-39 years, HIVST was lowest among adults aged 40 years and older for both men (34.4%, 121/352; PR 0.74, 95% CI 0.62-0.88) and women (30.0%, 136/454; PR 0.71, 95% CI 0.60-0.84). Women who were married, had children, had higher levels of education or were
wealthier were more likely to self-test. Men who had condomless sex in the last three months (47.9%, 279/582) reported higher HIVST prevalence compared with men who did not have recent condomless sex (43.1%, 94/218; aPR 1.37, 95% CI: 1.06-1.76). Among men and women, the level of previous exposure to HIV testing and household HIVST uptake were associated with HIVST.

**Conclusions:** Community-based HIVST reached men, younger age groups, and some at-risk individuals. HIVST was lowest among older adults and individuals with less previous exposure to HIV testing, suggesting the presence of ongoing barriers to HIV testing.

Key words: HIV self-testing, HIV testing, Malawi, men, population-based survey, causal associations

**Introduction**

Early diagnosis of people living with HIV (PLHIV) is critical to prevent new HIV infections. Knowledge of HIV status among PLHIV has rapidly increased in sub-Saharan Africa over the past decade. In 2017, 73% of PLHIV in Malawi knew their HIV status, of whom 90% were on treatment, of whom 91% were virally suppressed. However, the proportion of PLHIV aware of their HIV status is lower among men than women, with 68% of HIV-positive men diagnosed compared with 76% of HIV-positive women. Relative to older adults, adolescents and young adults aged 16-24 years also have poor knowledge of their HIV-positive status, increasing their risk of transmission and delay of treatment.

The majority of HIV testing services (HTS) in Malawi are provided at health facilities, though sex and age-specific barriers to facility-based HTS continue to exist. Men have lower rates of healthcare utilisation in general, reducing their opportunities to test for HIV through
routine services\textsuperscript{5}. Masculine norms might also lead men to underestimate HIV risk or symptoms of illness, prioritise economic obligations, stigmatise use of HTS, or fear knowing their HIV status\textsuperscript{5-8}. For adolescents or young adults, their status as dependents can limit their ability to consent or pay for HTS or generate fears of social and economic marginalisation from families following an HIV-positive diagnosis\textsuperscript{9-11}. Concerns around revealing sexual debut or stigma and discrimination from health care providers can also limit access to HTS\textsuperscript{9,10}.

HIV self-testing (HIVST) is an alternative strategy for reaching population sub-groups underserved by available HTS. In 2016, HIVST was recommended by WHO based on evidence of high acceptability, feasibility, accuracy, and uptake\textsuperscript{12}. Randomised trials in sub-Saharan Africa have demonstrated the effectiveness of HIVST on increasing HIV testing coverage in men and adolescents\textsuperscript{13-18}. The appeal of HIVST is that individuals are able to learn their HIV status in a convenient and discreet manner while achieving greater control and empowerment over the HIV testing process\textsuperscript{12,19}.

Providing HTS through alternative approaches is important to meet global treatment and prevention goals. Determining the characteristics of individuals who self-test for HIV is essential to understanding the added value of HIVST programmes in closing gaps in HIV testing coverage. Few population-based studies have examined characteristics of individuals who are accessing HIVST programmes in sub-Saharan Africa. Here, we assessed individual factors associated with self-reported ever HIVST within a community-based programme in rural Malawi.
Methods

Parent study: design, sampling and data collection

The parent study was a pragmatic cluster-randomised trial evaluating the effectiveness of community-based distribution of HIVST kits on uptake of HIV testing and antiretroviral therapy (ART) initiation (Clinical trial number: NCT02718274)\(^\text{15}\). The trial was delivered in rural Blantyre, Machinga, Mwanza and Neno districts in southern Malawi, which has an estimated HIV prevalence of 12.8%\(^\text{20}\). Twenty-two government primary health centres and their catchment areas were enrolled and randomised 1:1 to the community-based HIVST intervention or the standard of care. The study population included residents aged 16 years and older in health facility-defined clusters. Trial outcomes were assessed through population-representative surveys administered to cluster residents at baseline and endline. The trial is described elsewhere in detail\(^\text{21}\).

From September 2016 to January 2018, HIVST kits were delivered through community-based distribution agents (CBDAs), an established cadre of resident volunteers who deliver health commodities in Malawi. Implementation was led by Population Services International Malawi. Trained CBDAs promoted oral fluid-based kits door-to-door, with cluster residents aged 16 years and older eligible for HIVST. Informed consent to take an HIVST kit was waived by research ethics committees. Residents received an explanation on how to use the kit, interpret the results, and access onward HIV care and prevention services. Instructions were supplemented by a demonstration-of-use and instructional materials. CBDAs received a stipend for each kit distributed (MWK 100/USD 0.15). HTS and ART services could be accessed at health facilities as part of the standard of care.
The endline survey to evaluate the impact of the community-based HIVST programme was administered from October 2017 to January 2018. The survey used a two-stage sampling design. Evaluation villages meeting defined inclusion criteria were randomly selected per cluster. Households in each evaluation village were enumerated by research assistants and a variable proportion of households were randomly selected for the survey. A sample size of 250 individuals per cluster was calculated based on trial outcomes.

All individuals aged 16 years and older in selected households were eligible for the survey. Research assistants made multiple household visits to schedule interviews with eligible household members. Following informed consent or assent, individual-level questionnaires were administered to participants on sociodemographic characteristics, HIV testing and HIVST, and sexual behavior. The head of household or representative also completed a household-level module on socioeconomic status.

**Current study: outcome and exposure measurement**

The current study consists of secondary analysis of the endline survey administered in the 11 community-based HIVST intervention clusters. The outcome of interest was self-reported ever HIVST. We decided to use ever HIVST, in contrast to HIVST in the last 12 months, to ensure that HIVST uptake across the 14 to 17-month intervention period was captured, with limited prevalence (<1%) of HIVST reported at baseline\(^5\). Exposures included age group, sociodemographic factors (head of household, married, children), socioeconomic factors (educational attainment, household wealth status), sexual behavior factors (condomless sex in last three months), and health behavior factors (self-rated health status, number of HIV tests prior to the last 12 months, household uptake of HIVST).
A household wealth index was constructed using principal components analysis from an inventory of household and individual assets (Table 1, Supplemental Digital Content, http://links.lww.com/QAI/B485)\(^2\). Values were then divided into tertiles. Condomless sex with at least one sexual partner in the last three months was derived from a set of five questions on sexual behaviour and acted as a proxy for sexual risk (Table 2, Supplemental Digital Content, http://links.lww.com/QAI/B485). Number of HIV tests prior to the last 12 months was estimated using the difference between the number of lifetime tests and number of tests in the last 12 months. The measure was used to approximate exposure to HIV testing before the community-based HIVST programme. A binary measure for household uptake of HIVST was generated based on whether another household member reported ever HIVST.

**Statistical analysis**

Observations with missing age, sociodemographic or socioeconomic data were excluded from the analysis (Figure 2). As the outcome was common, we calculated prevalence differences using a binomial regression model and prevalence ratios (PR) using a Poisson regression model with a robust variance estimator\(^23,24\). Data analysis was stratified by sex, with factors associated with HIVST considered likely to vary given known differences in HIV testing coverage between men and women. Clustering was adjusted for using a fixed effect of health facility. P-values were obtained using Wald tests.

To test for causal associations between the exposures and outcome, we purposefully identified and adjusted for confounders using the conceptual framework in Figure 1\(^25\). Covariates were categorised and then ordered based on a hypothesised hierarchy of their relationship with the outcome, with more distal covariates considered likely to confound the
relationship between more proximal covariates and the outcome. Effect estimates were then adjusted for covariates higher in the conceptual framework, thereby likely not on the casual pathway, and associated with the outcome (p<0.10) in the unadjusted analysis. Specifically, models assessing sociodemographic or socioeconomic factors controlled for age. Models assessing sexual or health behavior factors controlled for age, sociodemographic and socioeconomic variables.

We used multiple imputation for the measure on condomless sex in the last three months due to the high proportion of missing observations. Our imputation model included variables thought to predict responses on sexual behavior, including age, sociodemographic variables, socioeconomic variables, cluster, and the outcome\textsuperscript{26,27}. We used 25 imputations based on the proportion of missing cases, and Rubin’s rules to obtain combined estimates from the imputed data\textsuperscript{27}.

Data were analysed in Stata version 14.0.

**Ethics statement**

The parent study received ethical approval from the London School of Hygiene & Tropical Medicine and the University of Malawi College of Medicine. Informed verbal consent for the endline survey was obtained for individuals aged 18 years and older. Individuals aged 16 and 17 years were asked to give verbal assent, with consent obtained from their parents or guardians.
Results

Response rate and sample characteristics

Household enumeration identified 4,285 individuals aged 16 years and older, with 3,355 individuals eligible for the survey following random household sampling (Figure 2).

Individual-level response rates were 69.5% (1,075/1,546) for men and 83.3% (1,507/1,809) for women, with most remaining household members unavailable. Of consenting men and women, 98.1% (1,055/1,075) and 96.6% (1,456/1,507) had complete data for age, sociodemographic factors, and socioeconomic factors, respectively.

Sample characteristics for men and women are described in Table 1. Distribution of age group was similar by sex. Relative to women, more men reported being the head of household or married, though fewer reported having children. Men were also more educated and resided in wealthier households than women. A higher proportion of men (72.8%, 582/800) reported having condomless sex in the last three months compared with women (56.5%, 608/1,077). The proportion of men who had not tested prior to the last 12 months (28.3%, 287/1,055) was also higher than women (19.1%, 260/1,456).

Self-reported ever HIV self-testing

Prevalence of self-reported ever HIVST was 45.0% (475/1,055) among men and 40.1% (584/1,456) among women. Cluster-level coverage of HIVST ranged from 26.5-69.6% for men and 23.1-66.0% for women. Further, 83.4% (880/1,055) of men and 89.1% (1,298/1,456) of women reported ever HIV testing.

A quarter of men (24.2%, n=255) had incomplete data on condomless sex in the last three months, of whom 40.0% (n=102) reported HIVST compared with 46.6% (373/800) of men
with complete data. Among women, 25.6% (n=379) had missing data, with 42.0% (n=159) self-testing in the missing group versus 39.5% (425/1,077) self-testing in the non-missing group.

The results of the multivariable regression models are shown for men in Table 2 and for women in Table 3.

**Age**

Age was associated with ever HIVST in both men and women, with evidence of a strong declining trend across categories of age. HIVST was higher among adolescent boys aged 16-19 years (50.7%, 70/138) than men aged 25-39 years (46.9%, 179/382), though the confidence interval included the null value (PR 1.02, 95% CI 0.84-1.22). A higher proportion of young men aged 20-24 years had also self-tested compared with adolescent boys (57.4%, 105/183; PR 1.2, 95% CI 1.02-1.41). Relative to women aged 25-39 years (41.3%, 217/525), HIVST appeared to be more prevalent in adolescent girls aged 16-19 years (46.4%, 97/209; PR 1.12, 95% CI 0.93-1.33) and young women aged 20-24 years (50.0%, 134/268; PR 1.15, 95% CI 0.99-1.34), though evidence for the effect was weak. HIVST was lowest among adults aged 40 years and older for both men (34.4%, 121/352; PR 0.74, 95% CI 0.62-0.88) and women (30.0%, 136/454; PR 0.71, 95% CI 0.6-0.84).

**Sociodemographic and socioeconomic factors**

Married women or women living with their partner (43.8%, 424/968) had higher prevalence of ever HIVST than women who were not married or cohabitating (32.8%, 160/488; adjusted PR [aPR] 1.26, 95% CI 1.09-1.46). Further, 40.5% (510/1,260) of women with children had self-tested compared with 37.8% (74/196) of women without children (aPR 1.38, 95% CI 1.0
Marital and parental status were not associated with HIVST among men. Across sex, there was no evidence that being the head of household was associated with HIVST (Tables 2 and 3).

Higher educational attainment and household wealth status were strongly associated with HIVST in women but not in men. Compared with women with no formal education (30.5%, 102/334), HIVST was more prevalent for women who had completed primary education (41.9%, 409/975; aPR 1.31, 95% CI 1.09-1.57) or secondary education or higher (49.7%, 73/147; aPR 1.66, 95% CI 1.29-2.13). In terms of household wealth status, a higher proportion of women in the highest tertile had self-tested (44.8%, 219/489) relative to women in the lowest wealth tertile (35.7%, 175/490; aPR 1.3, 95% CI: 1.12-1.52).

**Sexual and health behavior factors**

In the multiple imputation analysis, men who had sexual intercourse without a condom in the last three months (47.9%, 279/582) reported higher prevalence of ever HIVST compared with men who did not have recent condomless sex (43.1%, 94/218; aPR 1.37, 95% CI: 1.06-1.76). Among women, there was no evidence of an association between sexual risk and HIVST. Estimates were similar across multiple imputation and complete case analyses (Tables 2 and 3).

Frequent HIV testing prior to the last 12 months was strongly associated with HIVST in men and women. HIVST was more common among men who had previously tested 1-2 times (47.2%, 143/303) than men who had not tested (23.3%, 67/287; aPR 2.01, 95% CI 1.59-2.54), with increased HIVST based on the prior number of tests. Women who had previously
tested 1-2 times (39.2%, 164/418) also had higher HIVST prevalence compared with women who had not tested (18.1%, 47/260; aPR 2.03, 95% CI 1.52-2.71).

Living with a household member who ever self-tested was associated with HIVST. Among men, 64.4% (322/500) who reported household uptake self-tested compared with 27.6% (153/555) who did not report household uptake (aPR 2.09, 95% CI 1.8-2.43). Similarly, 57.5% (307/534) of women who reported HIVST among household members self-tested relative to 30.0% (277/922) of women who did not report household uptake (aPR 1.77, 95% CI 1.56-2.01).

There was no evidence that self-rated health status was associated with HIVST (Tables 2 and 3).

**Discussion**

The aim of this study was to understand: who is reached by HIVST? We found that self-reported ever HIVST was more prevalent among men than women. Uptake was lowest among adults aged 40 years and older. Women who were married, had children, had higher levels of education or were wealthier had higher prevalence of HIVST. Men who reported condomless sex in the last three months were also more likely to self-test. Among men and women, the level of previous exposure to HIV testing and household HIVST uptake were associated with HIVST. Given the limited number of population-based studies on HIVST, our study presents novel evidence on characteristics of individuals likely to self-test in the context of a community-based HIVST programme delivered in a high-prevalence, rural African setting.
Men form a disproportionate segment of people unaware of their HIV-positive status. HIVST provides a promising approach for reaching populations unwilling or unable to access facility-based HTS. We found that a higher proportion of men self-tested compared with women, indicating either higher acceptability of HIVST or greater need for HIV testing. Among men, 28.3% had never tested prior to the last 12 months compared with 19.1% of women. Further, men who reported condomless sex in the last three months had higher prevalence of HIVST. Ensuring that sub-groups with ongoing risk of HIV infection have access to repeat HIV testing is critical for HIV prevention and could be facilitated by HIVST. In urban Malawi, secondary distribution through sexual partners and community distribution through lay volunteers achieved high uptake of HIVST in men\textsuperscript{13,14}. Offer of HIVST beyond home-based HTS by community health workers increased knowledge of status by 5% among men in urban Zambia through primary and secondary distribution\textsuperscript{28,29}. We provide supporting evidence on the importance of extending HTS beyond health facilities to improve access and utilisation in men and at-risk sub-groups.

Our findings show decreased prevalence of HIVST across higher levels of age group. An earlier study of community-based HIVST in urban Malawi reported similar age patterns, with uptake of HIVST highest in adolescents and lowest in older adults\textsuperscript{13}. A mixed-methods study in Malawi and Zambia found that adolescents and young adults valued HIVST for providing greater autonomy and control over the HIV testing process, including the location and timing of testing and disclosure of results\textsuperscript{30}. An alternative interpretation suggests that adults age 25-39 years may be less likely to self-test than younger age groups due to availability of HTS through antenatal care. An important sub-group not routinely accessing facility-based HTS, but also less likely to self-test, are adults aged 40 years and older. Despite having the highest HIV prevalence, older adults may not test due to their roles as standard-bearers in their
communities and the perception that testing violates sexual decorum.\textsuperscript{8,31} Reported ageism among health care workers might also limit access of HTS.\textsuperscript{31} Ongoing barriers that inhibit utilisation of relatively convenient and confidential services need to be understood and addressed.

HIVST was more prevalent among individuals who shared a household with someone who reported HIVST, which may reflect the model of distribution, or imply the influence of social relationships on healthcare utilisation. Distributors provided HIVST kits through various approaches, including home-based distribution. As such, uptake by multiple individuals within a household may simply relate to the model of distribution, with preference for home-based distribution of HIVST kits previously described.\textsuperscript{30,32} Alternatively, there is potential for familial networks to influence uptake of HTS through information-sharing and support for HIVST and norms-setting around HIV prevention behaviors. A social network study found that Tanzanian men were more likely to test for HIV if they had a close friend who also tested, while they were less likely to test if they perceived HIV stigma to be present within their social network.\textsuperscript{33}

Lastly, HIVST was more likely among several sub-groups already reached by available HTS. Frequent HIV testing prior to the last 12 months was strongly associated with increased HIVST. Further, women who reported higher prevalence of HIVST had similar characteristics to those accessing facility-based HTS, that is married, more educated or wealthier women.\textsuperscript{34,35} Uptake among high-coverage and low-risk sub-groups can limit the cost-effectiveness of HIVST, as community-based programmes tend to be more resource and cost-intensive.\textsuperscript{36,37} HIVST programmes should therefore consider approaches to maximise complementarity, for example, implementing parallel community sensitisation and demand-
creation activities. The need for community mobilisation alongside distribution of HIVST kits is important to meaningfully engage underserved sub-groups and build their confidence to access and use HIVST kits.

The main strength of our study is the use of a population-based survey following large-scale, pragmatic implementation of community-based HIVST in a high-prevalence setting. Scale-up of HIVST remains relatively limited in sub-Saharan Africa, with our study providing a unique opportunity to explore uptake of HIVST in the general population. The intervention was delivered through CBDAs, a cadre common throughout Malawi. Our findings are mainly generalisable to similar African settings with equivalent cadres of community volunteers. Further, we used a theoretically-informed causal framework to identify and adjust for confounding factors and test for causal associations. While there are limitations to using observational designs for causal inference, we nevertheless provide important evidence on the characteristics of individuals reached by HIVST. Our study can help to inform provision of differentiated HTS to close remaining gaps in the HIV care cascade.

Our study includes multiple limitations. First, we used a self-reported outcome and exposures of interest, which may be prone to social desirability bias. Second, we may have potential ascertainment bias from non-participation. A quarter of eligible men were not available for the endline survey, potentially excluding men with irregular working hours or who migrate for work. Our data on condomless sex in the last three months also included a high proportion of missing observations, which we aimed to correct for using multiple imputation. Most models in our analysis, however, did not include the condomless sex measure and were not affected. Third, we used recent condomless sex as a proxy for measuring sexual risk, though it is possible that the reported sexual activity followed HIVST or occurred in stable
partnerships. We considered the latter by adjusting our analysis for marital status. Fourth, while we purposefully identified confounding variables using our conceptual framework, we may have some residual confounding. Fifth, we used frequency of HIV testing prior to the last 12 months to approximate exposure to HIV testing before the community-based HIVST programme. Ideally, we would have assessed HIVST among individuals who had not recently tested or were not diagnosed prior to the programme, but our survey did not allow this assessment. Finally, our results are limited to community-based distribution of HIVST kits, with factors associated with HIVST likely to differ by model. Components of our intervention design, including door-to-door implementation, reimbursements for CBDAs, and instructional materials, could influence our findings.

In summary, we analysed a population-based survey to provide insights into factors associated with ever HIVST within the context of community-based distribution of HIVST kits in rural Malawi. We found that community-based HIVST reached men, younger age groups, and some at-risk individuals. HIVST was also more prevalent among several sub-groups already accessing available HTS, including women who were married, more educated and wealthier. Understanding the characteristics of individuals who are likely to self-test is important to optimise HTS implementation and meet the needs of underserved sub-groups. In this study, HIVST was lowest among older adults and individuals with less previous exposure to HIV testing, suggesting the presence of ongoing barriers to HTS. Addressing these barriers, for instance through greater community engagement, will be critical to make the most of this promising strategy.
