ABSTRACT 350

Background. People living with HIV account for 38-50% of those affected in the 2022 multi-country mpox outbreak. Most reported cases had high CD4 counts and similar outcomes to those without HIV. Emerging data suggest worse clinical outcomes and higher mortality in more advanced HIV. We describe the clinical characteristics and outcomes of mpox in a cohort of persons with HIV and low CD4 cell counts (CD4 <350 cells/mm^3).

Methods. A network of clinicians from 19 countries provided data from confirmed mpox cases between May 11 and Jan 18 , 2023, in persons with HIV infection and CD4 counts <350 cells/ mm^3. We describe their clinical presentation, complications, and causes of death. Analyses were descriptive.

Findings. We include data of 382 cases: 367 cisgender men, 4 cisgender and 10 transgender women with a median age of 35 years. At mpox diagnosis, 349 (91.4%) were known to be living with HIV; 228/349 (65.3%) adherent to antiretroviral therapy (ART); 32/382 (8.4%) had a concurrent opportunistic illness. The median CD4 count was 211 cells/mm^3 (IQR 117-291); with 85 (22.3%) individuals with CD4 counts <100 cells/mm^3, and 94 (24.6%) 100-200 cells/mm^3. Of those with HIV viral load data available, 193/354 (54.5%) were undetectable. Severe complications were more common in persons with CD4<100 compared to those with >300 cells/mm^3, including necrotising skin lesions (54.1% vs. 6.7%), lung involvement (29.4% vs. 0%) occasionally with nodules, and secondary infections and sepsis (43.5% vs. 9.3%). Overall, 107/382 (28.0%) were hospitalised of whom 27/107 (25.2%) died. All deaths occurred in those with CD4 counts <200 cells/$mm^{3.}$ Amongst those with CD4 counts <200 cells/mm^3 more deaths occurred in those who also had high a HIV viral load. An immune reconstitution inflammatory syndrome to mpox was suspected in 21/85 (24.7%) persons

initiated or re-initiated on ART of whom 12/21 (57.1%) died. Sixty-two (62/382, 16.2%) received tecovirimat and 7 (2.2%) cidofovir or brincidofovir; three had laboratory confirmation of tecovirimat resistance.

Interpretation. A severe necrotizing form of mpox in the context of advanced immunosuppression appears to behave like an AIDS-defining condition, with a high prevalence of fulminant dermatological and systemic manifestations and death.

Funding. None

RESEARCH IN CONTEXT 635

Evidence before this study

In 2022, mpox, a disease caused by an orthopox virus referred to as monkeypox virus (MPXV) has caused outbreaks in 110 countries. Two distinct clades of MPXV, Clade I and Clade II, have existed in different geographic regions. The subclade IIb, identified in the 2022 outbreak, originates from subclade IIa mpox, which is considered a self-limiting disease. Unlike the previous epidemiological descriptions in West Africa, mpox transmission in this outbreak has been closely associated with the sexual networks of gay-and-bisexual men-who-have-sex-with-men (GBMSM), in which a high proportion of people are living with HIV. Some evidence suggests greater disease severity in people with advanced HIV. This finding warrants careful evaluation of the interplay between HIV, immune status and clinical manifestations of mpox. We searched PubMed for the terms "monkeypox, mpox AND (HIV)" from inception to Dec 31, 2022. Publications were predominantly letters, perspectives, case reports, and public health agency reports. In the multi-country outbreak, scientific publications of case series have described similar clinical outcomes in people living with HIV to those in people without HIV infection. However, most cases series included people with HIV and high CD4 counts (> 500 cells/mm^3) and suppressed HIV viral loads. In contrast, a Nigerian case series in the 2017-18 outbreak reported that more severe outcomes in hospitalized people were observed in persons living with HIV especially those who were viraemic and immunosuppressed. In a Center for Disease Control (CDC) report on 758 mpox cases in persons living with HIV during the multi-country outbreak (median CD4 639 cells/mm^3; 3% < 200/mm^3) 10% (68/758) were hospitalized for a median duration of 2 days (0-7). Worse rectal symptoms were described in those with HIV. A second CDC report identified adverse outcomes in 47 people with HIV and

mpox who had low CD4 counts, 12(26%) died and 5 deaths were attributed to mpox. Based on these data, individuals with HIV and advanced disease have been identified as cases requiring expert clinical advice, close surveillance and prioritised for anti-viral treatments such as tecovirimat, and preventive vaccines (where available).

Added value of this study

This mpox case series is the largest in those with advanced HIV disease. We characterized 382 persons with HIV and CD4 < 350 cells/mm^3. Individuals with lower CD4 counts presented with widespread, large, necrotising, and coalescing skin lesions. Some individuals also developed lung nodules without an alternative confirmed or suspected diagnosis. Severe secondary bacterial infections were common. Frequent and severe oral, ano-genital, and ocular presentations and complications are described. Immune reconstitution inflammatory syndrome (IRIS) was suspected in a quarter of those starting or re-initiating antiretroviral therapy (ART) after mpox diagnosis, 57% of whom died. The greatest disease severity, hospitalisation, and mortality was observed in individuals with both low CD4 count and high HIV viral load. This international case series includes 27 of the 60 persons reported to have died of mpox in the multi-country outbreaks, all 27 are persons with HIV and CD4 < 200 cells/mm^3.

Implications of all the available evidence

Our findings support the consideration of a severe, disseminated, and necrotising form of mpox infection as an AIDS-defining condition in CDC and WHO HIV disease classifications. This is based on the observation of protracted illness with fulminant disseminated necrotising

cutaneous lesions, systemic complications, and mortality in those with CD4 cell counts <200 cells/mm^3. Clinicians should also be aware that starting ART in people with advanced HIV and mpox may contribute to deterioration and possible death, possibly as part of an immune reconstitution syndrome. Our data reinforces the importance of HIV testing in mpox cases. Our findings support the recommendations that all at-risk persons with HIV with a CD4 count <200 cells/mm^3 should be prioritised for preventive mpox vaccination. There should also be consideration for use of potential mpox antivirals where available despite lacking data on their effectiveness and a concerted global effort to ensure access in countries without access to antivirals and vaccines.

BODY TEXT

INTRODUCTION 313

Since May, 2022, around 85,000 human mpox infections have been reported in 110 countries, with transmission predominantly through sexual contact amongst GBMSM.[1] The multi-country outbreak was declared a Public Health Emergency of International Concern (PHEIC) by the World Health Organisation (WHO) in July 2022.[2] People with HIV, accounting for 38-50% of persons diagnosed with mpox,[3] have been disproportionately affected.[3] Most persons living with HIV described in the 2022 case series had HIV viral suppression with median CD4 counts >500 cells/mm^3 and had similar clinical presentations, time to viral clearance, and outcomes to persons without HIV.[4–13]

Data from Nigeria and the USA suggest worse clinical outcomes in those with more HIV-related immunosuppression.[4,14,15] Two reports from Nigeria during the 2017-2018 outbreak suggested that people with advanced HIV presented with more severe or prolonged mpox. The first described that 4 of 7 deaths in 122 individuals with mpox, occurred in people with untreated advanced HIV.[14] The second report included 9 people with HIV with CD4 cell counts ranging from 20 to 357 cells/mm^3.[15] The authors described confluent rashes, higher rates of secondary bacterial infections and more prolonged illness.[15] More recently, a report from the US-CDC during the 2022 outbreak, confirmed these finding in 47 cases of severe mpox among people with advanced uncontrolled HIV infection.[16] All were hospitalized, had prolonged disease courses, or developed complications, and some had fatal outcomes (i.e., 5 deaths attributed to mpox).[16] Worse rectal disease was described in another CDC series in which 82% of people living with HIV were on ART and 72% were virally suppressed.[4]

Based on the existing data we hypothesized that in the current outbreak, mpox presentations and outcomes in persons living with HIV may differ by CD4 strata and HIV viral load. We leveraged global research networks to describe the characteristics, clinical course and outcomes of mpox in persons with HIV and CD4 count <350 cells/mm^3.

METHODS

Case definition and identification

Participating clinicians were recruited through the international research networks of the London-based Sexual Health and HIV All East Research (SHARE) Collaborative and the Network of the Skin Neglected Tropical Diseases and Sexually Transmitted Infections Unit of the Hospital Germans Trias i Pujol in Spain.[8–10] Researchers in geographic locations with high numbers of mpox diagnoses were approached and invited to contribute mpox cases diagnosed between May 11, 2022, and January 18, 2023. A confirmed case was defined as a polymerase-chain-reaction (PCR)-confirmed MPXV infection in a specimen from any anatomical site. We restricted this series to adults older than 18 years living with HIV and CD4 <350 cells/mm^3 or, in settings where a CD4 count was not always routinely available, HIV infection clinically classified as CDC stage C. We included people living with HIV and CD4 counts <350 cells/mm^3 in line with the widely accepted 2010 consensus statement which defines late presentation of HIV as CD4 <350 cells/mm^3 or an AIDS-defining illness.[17]

CD4 count was categorised as <100, 101-200, 201- 300, and 301-350 cells/mm^3, because CD4 count cut-offs of 100 and 200 are associated with different risk for opportunistic infections (e.g, cryptococcal meningitis is associated with CD4 < 100 cells vs. *Pneumocystis jirovecci* pneumonia (PJP) or toxoplamosis <200 cells).[18] For strata comparison, we grouped the seven individuals with a missing CD4 count with those who had a CD4 count < 100 cells/mm^3. Three of these had an AIDS-defining condition and four had a positive point-of-care qualitative CD4 count test [Visitect CD4 Lateral Flow assay providing a visually interpreted result of above 200 (negative)- or below 200 (positive)]. HIV viral load (VL) was categorised as undetectable (<50 copies/mL), 50-200 (low level viraemia), 200-<log4, ≥log4 log RNA copies/ml. We categorised the presence or absence of clinician reported complications by organ system.

Data collection

Each contributing centre completed a de-identified structured case-report sheet (CRS) adapted from one used in our prior case series to include variables of interest relevant to persons living with HIV and to capture more severe outcomes (Supplementary Figure 1). The CRS used drop down-menus and free-text fields to capture routinely collected data from electronic or paper medical records. The CRS focus on HIV status included CD4 cell count, HIV viral load, concurrent opportunistic infections, and adherence to ART. These data were included with information on mpox presentation, diagnosis, clinical features, complications, and outcome. We also considered four outcomes for management: outpatient, hospitalization, ICU-level care, and death. Duration of hospitalization was the number of days until discharge or until data collection if ongoing by the end of data collection.

Ethical considerations

Participating clinicians identified individuals living with HIV and diagnosed with mpox infection at their site. Informed consent for inclusion was obtained and maintained in accordance with local standards, along with local institutional review board approval as per each site's local requirement. Image-specific consent was obtained from participants (or their families when deceased) for the use of images. De-identified data were securely transferred to the coordinating site.

Statistical analysis

All analyses were descriptive, and no hypothesis testing was conducted. Continuous variables were described as the mean and standard deviation (SD) or median and inter-quartile range (IQR). Categorical variables are described as counts and percentages over the entire sample or the corresponding subgroup. No imputation methods were applied to missing data. Data were analysed using R version 4.2.1. Aggregate or de-identified data are presented to avoid deductive disclosure of the identities of study participants.

Funding

There was no specific funding for this study.

RESULTS

We describe 382 cases of human mpox infection in persons living with HIV with CD4 < 350/mm^3 from sites in 19 countries (10 in Europe, 8 in the Region of the Americas, and 1 in Africa) (Supplementary Figure 2). Most (72.5%; 277/382) were originally from the Americas

(Argentina, Brazil, Canada, Chile, Ecuador, Mexico, Peru, USA), 25.9% (99/382) were from the European region (Austria, Belgium, France, Germany, Greece, Italy, Portugal, Spain, Sweden, Switzerland, UK), 1.6% (6/382) from Africa (Nigeria).

The demographic and epidemiological characteristics of the participants are described in Table 1. The median age was 35 years (IQR 30–43). Three hundred and sixty-seven out of 382 (96.1%) identified as cisgender men, 4 cisgender women (1.0%), 10 transgender women (2.6%), and 1 non-binary individual assigned male at birth (0.3%). The ethnicity or race of participants as described by the attending clinician was Black 14.4% (55/382), Latin-American 58.9% (225/382), or White 22.3% (85/382).

Overall, 349/382 (91.4%) were known to be living with HIV prior to mpox diagnosis, and 33/382 (8.6%) were newly diagnosed with HIV infection at the time of the MPXV infection. Of those known to be living with HIV, 84.5% (295/349) were on ART and 65.3% (228/349) were reported as adherent to treatment in the preceding six months. The median CD4 cell count was 211 cells/mm^3 (IQR 117-291). The distribution of CD4 counts was as follows: 85 (22.3%) <100 cells/mm^3, 94(24.6%) 100-200 cells/mm^3, 128(33.5%) 201-300 cells/mm^3, and 75 (19.6%) 301-350 cells/mm^3. CD4 counts were missing in 7 individuals who were assigned to the group with CD4 <100 cells/mm^3as described in the methods and in Table 1,2,3. Overall, 193 individuals (50.5%) were virally suppressed (HIV RNA <50 copies /ml), 26 (6.8%) had low-level HIV viraemia (50-200 copies/ml), 30 (7.9%) had viraemia from 200 to log4 copies/ml, and 105 (27.5%) had viraemia of > log4 copies/ml. HIV RNA values taken within the past 6

months were not available for 28 individuals (7.3%). Overall, 8.4% of patients (32/382) had a concurrent opportunistic infection at the time of the mpox diagnosis.

In terms of clinical presentations (Table 2), 243/382 (63.6%) patients had fever and 364 (95.3%) had a skin rash, which was initially vesiculo-pustular in 297/382 (77.7%) and progressed to ulcerative in 84/382 (22.0%). The median number of skin lesions was 15 (IQR 8-35), and the median duration to resolution was 23 (IQR 18-33) days. Among 36 patients (9.4%) who had 100 or more lesions and 43 patients (11.3%) who had a duration to resolution of forty days or more, the majority had CD4 counts <200 cells/mm^3 and detectable HIV plasma viral loads (Supplementary Figure 3 & 4). Overall, 235 individuals (61.5%) had genital, 203 (53.1%) anal lesions, 144 (37.7%) oral involvement and 20 (5.2%) had ocular involvement. The most common organ complications were dermatological, respiratory, and secondary bacterial infection (Table 2). A total of 94/382 (24.6%) patients developed dermatological complications; 10 (2.6%) of these were ecchymotic or haemorrhagic lesions, and 84 (22.0%) were necrotising lesions, of which 55 (14.4%) were coalescing. The most common presentation was multiple, large (typically greater than 2cm in diameter), rounded ulcers with necrotic centres and a fresh, raised border, located close to the oro-genital regions (Figure 1B. Photographs B1-4) or in distant locations (Figure 1B. B6-8), while verrucous appearance (Figure 1B. B5) was rare. In many instances, erythema and oedema surrounded the ulcer. Lesions involving the mouth, eye, or anus resulted in functional impairment (B1-4). In the anogenital region, some individuals presented with significant tissue damage and phagedenic ulcerations (Figure 1C). Some persons had progression to target-shaped lesions with erythema, swelling and pallor beyond the margins of the ulcer indicating severe necrosis. (Figure 1C) Pseudo Koebner phenomena (i.e., the spread of the skin infection along sites with

skin microtrauma or rubbing) were manifested by ulcers exhibiting a lineal distribution or overlying bony prominences . In cases where epithelialization had occurred, tissue destruction resulted in disfiguring scarring (Supplementary Figure 5 &6, and Dermatology Atlas).

In total, 35/382 (9.2%) people presented with respiratory complications (Supplementary Table 1). Of these, eleven individuals (2.9%) presented with numerous bilateral diffuse pulmonary nodules; 4/11 diagnosed with an X-ray only, and 7/11 were further characterized on CT scanning. All the radiographic images were reviewed by two specialist radiologists who concurred that these nodular lesions were unusual and characterised by well-defined borders, absence of cavitation and no adjacent areas of ground glass shadowing; most of the nodules were peri-vascular suggesting hematogenous spread and, generally, ranged in size from of 5 to 20 mm. In all three patients with nodules in whom BAL or lung biopsy were performed, a positive MPXV PCR result was obtained (with negative microbiological results for *P. jirovecci* and *M. tuberculosis)* (Figure 1A). 8/11 had a CD4 count below 100 cells/mm^3.

12/35 (34.3%) individuals with respiratory complications had dyspnoea of whom - two had normal chest X-rays, and ten had no available radiology report. Additionally, 6/35 (17.1%) individuals presented with pleural effusion (1 with a positive MPXV PCR on BAL), and 3/35 (8.6%) with ground glass changes (2 with suspected opportunistic infections; 1 with a positive MPXV PCR on BAL).

Twelve (3.1%) individuals were reported to have neurological involvement (Supplementary Table 2), including one (0.3%) case classified as encephalitis with orbital, frontal and temporal oedema on CT scan, and with a positive MPXV PCR result, and negative HSV-1 and 2, and VZV results in cerebro-spinal fluid (CSF). Of the nine (2.4%) cases with altered mental status or confusion six had normal CSF and/or radiological findings and three did not undergo imaging or CSF examination. In five cases confusion was attributed to sepsis, in one to respiratory failure in one to hepatic encephalopathy, and the cause was undetermined in two cases. Neurological symptoms were almost exclusively described in persons with HIV with CD4 less than 100 cells/mm^3.

In 76/382 (19.9%) individuals, secondary bacterial infections were diagnosed, including cellulitis, abscesses, and sepsis. Among 17 patients with sepsis, 8 had positive blood cultures and the following pathogens were identified: three *Pseudomonas aeruginosa*, two ESBL *E. coli*, two polymicrobial, and one *Shigella flexneri.* Additionally, 12 patients had a positive result from an abscess or deep wound sample culture: three *Pseudomonas aeruginosa*, two *Klebsiella pneumoniae*, two ESBL *E. coli*, three methicillin-sensitive and two methicillin-resistant *Staphylococcus Aureus*.

All complications were more common in individuals with CD4<100 compared to individuals with CD4>300 cells/mm^3. This included dermatological (57.6% vs. 9.3%), respiratory (29.4% vs. 0%), CNS (10.6% vs. 1.3%), bacterial infection (43.5% vs. 9.3%), ocular (15.3% vs. 1.3%), gastrointestinal (27.1% vs. 6.7%), rectal complications(56.5% vs. 28.0%), oropharyngeal (34.1% vs. 24.0%), and genito-urinary 34.1% vs. 9.3%) (Figure 2A).

Overall, 107/382 (28.0%) individuals were hospitalised; of these, 7 (1.8%) survived an admission to intensive care and 27 (7.1%) died (Table 3). Among the 27 people who died, the median CD4 count was 35 cells/mm^3 (IQR 24-100), and the median HIV viral load was 5 log copies/ml (IQR 4-5), only one patient was HIV virologically suppressed. Among those who died, severe necrotising or haemorrhagic skin lesions occurred in 25/27 (92.6%), bloodstream or deep tissue bacterial infections (24/27; 88.9%), respiratory symptoms and respiratory failure (23/27; 85.2%), neurological (8/27; 29.6%), rectal (21/27; 77.8%), and oropharyngeal (18/27; 66.7%) involvement were described (Table 3). Ocular disease occurred in (13/27; 48.1%), 8 of whom had peri-orbital cellulitis. The reported cause of death was septic shock and multi-organ failure in 20/27 (74.15%), respiratory failure 4/27 (14.8%), disseminated mpox in 2/27 (7.4%) and cardiac arrest in 1/27 (3.7%).

Rate of hospitalisation and ICU admission increased with declining CD4 counts and rising viral loads (Figure 2). No deaths occurred in individuals with CD4 counts >200cells/mm^3. Mortality was incrementally higher among people in the lowest CD4 strata (CD4<100 27.1% vs. CD4 100-200 4.3% vs. CD4>200 0%; Figure 2B) and amongst those with the highest viral loads (HIV VL log≥4 16.2% vs. HIV VL undetectable 0.5%; Figure 2C). In those with CD4 count <100 cells/mm^3 (n=85) and available HIV VL, the death rate was 7.1% (1/14) for individuals with VL <50 copies/ml and 29.8% (14/47) for those with HIV VL ≥4 log copies/ml.

Among 85 persons started or restarted on ART, in 21 (24.7%) the managing clinician suspected IRIS as a cause for clinical deterioration (Supplementary Table 3). Of these, 6

(28.6%) were newly diagnosed and 15 (71.4%) were known to be living with HIV but either not receiving or not adherent to ART. All had CD4 count <200 cells/mm^3. The median time from onset of mpox symptoms to the start of ART was 21 days (range 0-73), and from the start of ART to worsening of mpox symptoms was 14 days (range 3-64). Nine of 21 (42.9%) were treated for IRIS with steroids, and 10 (47.6%) received supportive care. Of those with suspected IRIS, 3/21 (14.3%) were admitted to the ICU, 5 (23.8%) were hospitalised in a general ward, and 12 (57.1%) died.

Forty-three (41.7%) of the 103 hospitalized patients and twenty-one (7.5%) of the 279 outpatients received antivirals to treat mpox. Sixty-two (62/382, 16.2%) individuals received tecovirimat (5 received both oral and IV) and 7 (1.8%) cidofovir or brincidofovir. All patients receiving mpox-specific antiviral therapy were treated in Europe or the USA, except two who received tecovirimat in Brazil. Laboratory confirmation of tecovirimat resistance (presence of FL13L mutations by sequencing) was detected in 3/5 people tested, who had severe immunocompromise, disseminated and progressive mpox infection despite prolonged treatment (>14 days) with tecovirimat and finally died. Sampling for resistance testing was conducted after at least one course of tecovirimat had been completed. Nobody who died had received mpox-vaccination prior to or during 2022.

DISCUSSION

Our large case series describes a severe, disseminated form of mpox infection with 15% mortality in individuals with advanced HIV-related disease characterised by CD4 counts below 200 cells/mm^3. This fulminant form of mpox is characterized by massive necrotising skin,

391 genital and non-genital cutaneous and mucosal lesions, sometimes accompanied by lung
392 involvement with multifocal nodular opacities or respiratory failure, severe cutaneous and
393 bloodstream secondary bacterial infections. The severity of oral and anogenital complications
394 are more marked than previously described.[4–10,19] As described in the CDC classification,
395 disseminated forms of coccidiodomycosis, histoplamosis and mycobacterium avium complex
396 are considered to be AIDS-defining illnesses.[20] Very similarly, we describe that people with
397 the lowest CD4 counts (<100 cells/mm^3) and highest HIV viral loads (> 4log c/ml) had
398 disseminated forms of mpox strongly suggesting that this severe necrotising form of mpox
399 with systemic involvement is also an AIDS-defining condition (Supplement Table 4).[20] We
400 describe in detail the clinical course of 27 people with CD4 counts < 200 cells/mm^3 who died,
401 representing more than 40% of all mpox deaths reported in 2022. We also wish to raise
402 awareness of the 57% mortality rate in those in whom IRIS was suspected following ART
403 initiation/re-initiation.
404
405 This data builds on the observations of the altered natural history and course of mpox that is
406 emerging. To date most information about the intersection of HIV and mpox reports on those
407 with well-controlled HIV infection.[4–11] During the 2022 multi-country outbreak even the
408 largest series include very few people living with HIV and CD4 counts < 350/mm^3 (12%) or
409 <200/mm^3 (3%).[4,21,22] We hypothesized that mpox may have a different clinical presentation
410 in individuals with advanced immunosuppression, as can be the case with some pathogens.
411 Although the self-limiting clinical course in individuals with well-controlled HIV is very similar
412 to that of individuals without HIV, our series provides evidence that the disease is very
413 different in those with advanced HIV. The protracted duration and larger number of skin

lesions in these individuals also raises the possibility of a more prolonged period of infectivity, but further studies are needed to investigate this.

Prior work has shown that people living with HIV with high CD4+ T-cell counts (>350 cells/ mm^3) mount a poxvirus-specific T-cell response that is similar to those without HIV infection,[23] but there are no data on immunological responses in those with low CD4 counts (<350 cells/ mm^3). In our series low CD4 cell count especially when < 200/mm^3 was strongly associated with increasing severity of mpox disease relative to those with CD4 200-350/mm^3 and compared to previous reports where CD4 > 500/mm^3. Data from animal model MPXV studies have shown that CD4 depletion before immunisation of non-human primates decreased the development of protective B-cell responses and antibodies, and increased infection severity after monkeypox virus challenge, which is consistent with our findings.[24] Moreover, in our series, the effect of a low CD4 count on severity or death varied with the HIV plasma viral load, with higher viral loads associated with increased frequency of severe illness in any given CD4 group. Prior work has shown that replicating HIV virions target antigen-specific T cells that are activated to combat other pathogens, resulting in impaired T-cell responses.[25–27] Thus, it is possible that a substantial fraction of MPXV-specific CD4 T cells might die or be impaired due to either complete or abortive HIV infection. Others have shown impaired immune responses to hepatitis B and other vaccines in those with low CD4 and unsuppressed HIV virus replication, providing further evidence that HIV replication may interfere with immune response to other pathogens.[27,28] Based on our findings we believe that a severe necrotising form of mpox with systemic manifestations exists. This form of mpox affected those with CD4 counts <200 cells/mm^3 - the precise CD4 threshold considered to be AIDS-

437 defining in international guidelines (Supplement table 4). Given the 15% mortality in this
438 group, strong consideration should be given to designating this disseminated form of severe
439 mpox as a new AIDS-defining condition in definitions and guidelines.
440
441 Several limitations of our research need to be highlighted. Our data are derived from an
442 observational retrospective convenience case series from countries with high numbers of
443 mpox infections. We were, therefore, unable to assess how well our cohort represents the
444 entire population of people living with HIV and who developed mpox infection. Study sites
445 may have been more likely to include individuals with more severe outcomes which may have
446 biased the relationships we saw between both CD4 counts and HIV viral load and clinical
447 outcomes. Individuals included in this case series had symptoms that led them to seek
448 medical care; therefore, persons who were asymptomatic, had milder symptoms, or lacked
449 access to medical care could have been missed and thus we may have overestimated illness
450 severity.[29] Also outcomes may have been missed if people reattended with severe disease at
451 different sites that were not part of the case series. Due to data collection from multiple sites
452 some characteristics may have been collected in a heterogeneous manner, and laboratory
453 techniques also differed from site to site. Many of the cases had a concomitant opportunistic
454 infection and it may be difficult to ascertain many of the outcomes to mpox relative to the
455 other pathogens. For example, some healthcare settings included did not have access to
456 certain radiological and microbiological investigations so we cannot be certain of the role of
457 mpox as opposed to other opportunistic infections. However, we suggest that the coincident
458 perivascular non-cavitating lung nodular pattern described by two radiologists and seen in
459 eleven patients, without a documented suspicion or microbiological evidence of a co-

opportunistic pathogen, may be a manifestation of mpox disease and further research is warranted.

Many of the deaths were associated with multiorgan system failure, and the relative contribution of the mpox to death unclear. We have raised the possibility of IRIS reactions with the initiation of antiretroviral therapy but in the absence of a strict definition and in the absence of details on confounding conditions that may have contributed to adverse outcomes the data are uncertain. Data are currently not available from randomised controlled clinical trials on the impact of MPXV antivirals or preventive vaccines on the course of mpox, and with the limited use in this series their role cannot be evaluated.

Physicians caring for persons with mpox and advanced HIV disease must be made aware of the severe outcomes and high mortality that can occur especially when cutaneous and bloodstream bacterial super-infection set in. Clinical trials tailored to this group are needed to evaluate the impact of antiviral agents and preventive vaccines to modify disease outcomes. In the absence of these data, persons with HIV, low CD4 counts who need to be hospitalised with mpox should be considered for expanded access to these therapies where available. We have raised the risk of deterioration after initiation of antiretroviral therapy that carried a 57% mortality rate. This needs to be considered when caring for persons with HIV and advanced disease with mpox who are not on therapy. Further research into the role of IRIS is necessary to better understand the role of potential interventions, such as early versus delayed initiation of ART, the concomitant use of steroids or other immunomodulatory strategies leading to a reduction in the frequency of IRIS.

Our data also reinforces the recommendation that HIV testing (in addition to other sexual transmitted pathogens) be performed in every case of mpox. Further those with HIV infection and high risk for mpox infection should be prioritised for preventive vaccine. Two thirds of the deaths we have reported have occurred in Latin America. Our findings are particularly pertinent for countries with low levels of HIV diagnosis and/or without universal free access to ART and intensive care units, where the interaction of uncontrolled HIV infection and mpox is more prevalent. In these countries, a concerted effort to provide urgent access to mpox antivirals and vaccines is of vital importance.

CONTRIBUTORS

OM and CMO conceived and designed the study. CMO, and OM co-ordinated the global collaboration. AA and CGC managed the global data collection. CMO, OM, AA, MM, CGC developed the case report form. MM and OM analysed and interpreted and vouch for the data. All authors except MM, and CMO submitted cases. OM, CMO, AA, CGC and MM drafted the first draft of the manuscript. CGC and JV prepared the image library. SW edited the final draft. All authors reviewed the manuscript and vouch for the accuracy and completeness of the data. All authors were responsible for the final decision to submit for publication and have seen and approved the manuscript. CMO, MM and OM had full access to all data.

DATA SHARING

De-identified participant data collected, including individual participant data, and will be made available from the corresponding author on reasonable request.

DECLARATION OF INTERESTS

We declare no competing interests.

ACKNOWLEDGMENTS

We thank Roser Escrig for her assistance in administering data sharing agreements, and Gerard Carot-Sans for providing comments to the manuscript. We would like to thank the Swiss HIV Cohort Study network, who made possible and facilitated data collection. We wish to acknowledge Dr Maria Beiras-Garcia, Department of imaging and Radiology, Complejo Hospitalario de Pontevedra, Pontevedra, Spain for reviewing and commenting on the radiological images. Thank you to the individuals with mpox and families of deceased individuals who graciously consented to contribute data to further knowledge of this disease.

FIGURE LEGENDS

FIGURE 1. Skin presentation of mpox in advanced HIV disease

Panel A: Disease progression in a patient with CD4 count of 18 cell/mm3 and viral load log5, with pcr- confirmed lung involvement, bowel perforation, IRIS, and death despite having received two courses of IV tecovirimat and one course of IV cidofovir.

Panel B: Photographs of necrotizing lesions in multiple patients. Lesions of the skin and mucous membranes. **B1**: Necrotic ulcers in the peri-labial and nasal areas. Ulcer with tissue destruction on the right upper lip. **B2**: Umbilicated vesiculopustular-like lesions on upper eyelid surrounding an extensive necrotic ulcer. Eyelids and nasal radix with oedema and erythema. **B3**: Mucositis, oedema and erosions of the labial mucosa and tongue. **B4:** Necrotic ulcers with raised edges, some confluent, on the scrotum, dorsum of the fingers, groin, and thighs. **B5:** Numerous verrucous, excrescent, yellowish facial lesions. **B6:** Multiple periumbilical target-like vesiculopustular lesions, with necrotic depressed centre and erythematous halo. **B7**: Large, necrotic, and confluent ulcer on the elbow surrounded by small numerous vesiculopustular lesions. **B8**: Necrotic ulcers, oedema and erythema on the left hand and wrist.

Panel C: Before and after lesions, with progression to severe confluent target-shaped ulcers with dark necrotic centre surrounded by a vesiculopustular halo and peripheral oedema, in the perianal area and back.

Legend: All deceased individuals were cis male, except for patient 16 and 24 that were cis female.
None had received smallpox vaccination before 2022 or had been vaccinated as pre-exposure or post-exposure since May 2022. * Since ventilation was often unavailable, answering "no" does not necessarily mean it was not needed.
IMV – Invasive Mechanical Ventilation, NIV – Non-Invasive Ventilation
*Clinical suspicion, not microbiological confirmation
